Different species of plants and consumers within the food web and specific environmental conditions (such as warm temperatures, low concentrations of nutrients, and high pH) influence rates of internal cycling. Land-use practices also have a large effect on vegetation and on how nutrients recycle within a catchment or move into streams and lakes. For example, by measuring the concentrations of nutrients in a stream draining forested catchments, a team of ecologists (led by Gene Likens and Herbert Bormann) identified different pathways for nutrients such as gaseous nitrogen and erosional phosphorus in Hubbard Brook, New Hampshire, from a series of long-term studies on the forest and its components (streams, lakes, and catchments). The research at Hubbard Brook demonstrated the importance of large-scale experiments (such as removal of forest vegetation) to determine how various components are related. The increased outputs of some major nutrients (nitrogen, phosphorus, and calcium) following the experimental manipulation of the forest cover provided information about the role of trees in taking up and storing water and nutrients. By tracking the movement of phosphorus out of the forest and into the stream, Judy Meyer concluded that pulses of stream flow were the primary mechanism governing movement of this relatively scarce element. Phosphorus can be stored by mosses and other plants in their biomass. Later studies led others to recognize the generality of Meyer’s observations in 1979 and to identify the important role that aquatic mosses play in taking up and storing phosphorus in stream ecosystems as well as providing microhabitats for many types of benthic invertebrates. These studies at Hubbard Brook and elsewhere later became important in understanding how calcium biogeochemistry and acid deposition altered the forests, soils, and stream chemistry. Comparative watershed studies were conducted by researchers at several sites, such as the Coweeta Hydrologic Laboratory in North Carolina, the H.J. Andrews Experimental Forest in Oregon, and the Kuparuk River at the Toolik Lake Long Term Ecological Research site in the Alaskan tundra to track changes in mineral cycling as food webs responded to experimental manipulations of nutrient inputs.

Loops, Spirals, and Chains

Different species can be complementary in their roles as they interact in obtaining their energy. For example, benthic species transfer nutrients deposited in the sediments and stored in organic detritus back into overlying waters and thus help

move the stored energy up food chains and to other associated food webs. Burrowing and mixing of sediments by benthic species enhance productivity of freshwater ecosystems and lead to interconnected food webs. The rate of movement from one form to another can be facilitated by how species use resources in different ways. Size differences in the resources and the species can be extremely important.

Microbial species play especially effective roles in internal nutrient cycling by using organic detritus as an energy source. Their small size and fast turnover (biomass: productivity ratios) of carbon and nitrogen make them highly important. Bacteria and fungi rapidly break down dead organic matter before it accumulates within terrestrial soil and aquatic sediment (benthic) ecosystems. In many soil, stream, and estuarine ecosystems the amount of energy and nutrients cycled by microbes is relatively larger than that of the photosynthetic pathway. The soil and sediment biota have similar groups of specialized species that shred organic detritus (from leaves, fine roots, dead algae, and other small invertebrate consumers). Fine particulate organic matter (FPOM) is composed of small fragments of detritus and aggregates of dissolved organic matter (DOM) that form from breakdown products and from cell exudates and leachates in aquatic ecosystems (such as groundwaters, streams, lakes, and estuaries). The release of DOM and inorganic nutrients is accelerated by some species of microbes and is a source of energy and nutrients for other microbial species, such as bacteria, fungi, and ciliated protozoans. DOM is also a food resource for larger invertebrate consumers and provides a parallel set of pathways for energy flow.

Invertebrate detritivores break down dead organic materials to obtain their energy. Many detritivores are dependent on microbes to condition the detritus before it can be consumed by invertebrates or vertebrates. Nutrient cycling allows for continued energy flow through the ecosystem. The continued input and flow of energy through the food web is likewise required for nutrient uptake and recycling. Numerous species of bacteria and fungi form a “microbial loop” that provides for high rates of energy flow by breaking down organic matter. Excretion of wastes by consumers provides one source of nutrients for species in the microbial loop. The microbial loop is especially important in marine and freshwater pelagic (open-water) ecosystems. For example, a crater lake (e.g., Crater Lake, Oregon) with a limited surface area and positioned in a volcanic depression usually has a very small drainage basin compared to large lakes with extensive drainage runoff. A lake with a small surface area will also receive very little atmospheric inputs of nutrients. Primary production remains low and mostly dependent on rapid, internal recycling of nutrients from fine, suspended detritus (dead plankton) as a result of breakdown by microbial species. Nutrients may only slowly accumulate in the sediments of the deep Crater Lake and not be mixed by currents back into the upper layers of well-lit waters (photic zone). Whenever nutrients are low (as in midsummer in some more productive lakes following the spring bloom of algae) the role of microbes and invertebrate species in cycling nutrients is important to maintaining energy flow in the ecosystem.

Similarly, nutrient concentrations are relatively low in the open ocean, far away from continental sources of nutrient

runoff and from coastal upwellings of deeper, nutrient-rich waters. Microbes attach to dead plankton and use this organic detritus as a source of energy. In the process of breaking down this fine detritus, the microbes release nutrients for further growth by phytoplankton (floating algae). Nutrients are also released in the photic zone by leakages from algal cells and by excretion of herbivores. The small size of the detritus particles slows their rate of sinking through the well-lighted photic zone and allows the microbes to release nutrients where phytoplanktonic photosynthesis is not light limited. Larger pieces of detritus fall more rapidly and accumulate in deeper, darker waters where short-term seasonal storage occurs. The nutrients in these deep, dark waters are not available for continued photosynthesis until this entire layer of nutrient-rich water is mixed vertically by wind- and gravity-driven currents back into the photic zone and taken out of temporary, seasonal storage. In very deep lakes, the wind energy is insufficient to mix the entire volume and nutrients accumulate over many years in these deep waters.

There are also some important horizontal linkages in that nutrients and organisms (especially differently sized fishes and wind-driven currents carrying drifting zooplankton) move from the shallow, nearshore waters (littoral zones) of lakes to the open waters (pelagic zones). In these surface waters, nutrients are also recycled by the grazing zooplankton (feeding on phytoplanktonic algae) and by consumption of zooplankton and phytoplankton by fishes. These nutrients are returned to the well-illuminated surface waters, where they are again available for continued algal growth.

This series of vertical and horizontal transformations of organic detritus and primary production of algae in the pelagic zones has some similar analogs in streams, in which the dynamics occur mostly horizontally, but to some extent vertically, along the network of stream channels. The combined vertical and horizontal currents in stream channels form a spiral in the downstream flow of water that carries nutrients and organisms to various distances. Dissolved nutrients move in and out of solution as they are briefly taken out of solution by adsorption on sediments and by active uptake by microbes and attached algae (growing along the bottom of the channel), and are later consumed and released back into the water by cell leakage, excretion from grazers, and predatory fishes. This spiral pattern of nutrients being transported downstream while moving in and out of sediments and organisms and then taken up again by other organisms or adsorbed onto sediment particles farther downstream was first examined by ecologists at the Oak Ridge National Laboratory using isotopes to trace pathways and is now widely studied, for example, with stable isotopes of nitrogen (N^{15}). The distance that a particular nutrient element such as nitrogen moves downstream is termed the "spiral length." If the nutrient is taken from solution and tightly held in different species' biomass, then the spiral length is relatively short and the role of microbes and other organisms along the channel is relatively important compared to that for streams where biotic interactions are less significant and during other periods when the spiral length is longer.

Use of functional groups such as shredders and filter feeders (or scrapers, burrowers, and predators) allows for analysis of groups of different species in terms of particular

attributes (e.g., how each species processes different sizes of detritus). In both vertically and horizontally structured interactions, the processing rate of organic detritus by microbes is accelerated by the presence of those invertebrate species that convert large organic fragments into finer fragments. If one species (shredders) uses larger sizes of suspended particles and breaks them down into smaller particles as a result of its feeding, then the downstream supply of FPOM is increased for use by other species (filter feeders). However, if the species that shreds detritus is lost, the filter-feeding species may not function effectively. Different species may form "processing chains" that require particular combinations of linked-species to complete certain ecosystem processes efficiently. These processing chains are one way that increased species diversity can increase efficiency of processing detrital resources, especially if detritus is available at low levels of abundance or if the detritus quality is low. Similar linkages are known to occur among burrowing organisms in soils and sediments where strong interactions are generally important in understanding how different ecosystems function.

Biodiversity Effects on Energy Flow

Productivity and related ecosystem processes such as nutrient cycling and decomposition are generally known to be influenced by particular species. Species attributes, including length of life span, rates of dispersal, and tolerance of frequent and intense disturbances under various environmental conditions, have important effects on ecosystem processes. Key processes (such as nitrogen fixation) performed by only a limited number of species or particular modes of feeding characteristic of only a few species are recognized as important characteristics associated with biodiversity. The importance of a single species in biogeochemical cycling was demonstrated by Peter Vitousek and his students in studies of the invasion of some habitats in Hawaii by the nitrogen-fixing plant *Myrica faya* and by determining the long-term consequences for nitrogen cycling and impacts on the ecosystem. These landscape changes in the biomass production and species composition are now being studied over large scales by use of remote sensing technology (MODIS satellites and airborne sensors such as LiDAR).

David Tilman and others conducted several experiments to test the hypothesis that primary productivity in prairie grasslands is related to the number of species of plants grown in the same plot. These experiments and others have the advantage of considerable replication and careful controls but were conducted at relatively small scales. Although the relationship between species richness and energy flow in ecosystems has attracted considerable study, the scale of these experiments and the composition of the species assemblages studied have resulted in different interpretations of general relationships. Results of field tests suggest that the number of species per se is apparently not as important as the particular attributes of different species that relate to their efficiency of nutrient uptake and retention, as well as growth. The larger the number of species included in a study, the more likely some species will be included that are well adapted for the conditions and function effectively. Thus, although ecologists have conducted

field tests to determine how different species alter ecosystem processes, there is no complete consensus on how energy flow by itself influences species richness or vice versa. Part of this lack of consensus is a result of using different scales and methods in field studies of many different types of ecosystems (e.g., boreal and tropical forests, grasslands, deserts, deep and shallow lakes, and large and small rivers). Theoretical and conceptual developments are being actively developed and are stimulating additional field testing of these relationships between biodiversity and productivity.

Top-Down and Bottom-Up Regulation of Energy Flow

In the 1960s, some of the first experiments designed to identify the importance of different species and key attributes included the removal of predators. Because top predators are relatively few in numbers, their removal can be operationally feasible over some relatively large areas. Robert Paine removed predatory starfish from the intertidal zone and observed a shift in the relative and absolute abundances of some of the molluscan prey species. His results demonstrated that competing species can be held in check by selective predation, especially if the predators consume more individuals of the more numerous prey species. Work by James Estes in the 1970s on the effects of declines in abundances of sea otters and increased abundances of sea urchins and other prey (as well as the shifts of algal regrowth in kelp beds) along the west coast of North America also demonstrated that predators had large effects on entire food webs. These “keystone species” were viewed as important regulators of energy flow in natural food webs in that they had a disproportionate effect despite their relatively small numbers or biomass. The declines in top, apex predators (overharvest, habitat loss, or disease) can lead to a cascade of effects throughout the food web.

Recognizing the importance of keystone species led some ecologists to use this idea for managing certain ecosystems. Researchers introduced the concept of bio-manipulation to study different combinations and abundances of algal species and grazing species in order to regulate nutrient cycling in aquatic ecosystems. In a series of lake studies by several ecologists (especially Joseph Shapiro, J. Hrbacek, John Brooks, and Stanley Dodson), they controlled the presence or absence of top fish predators. From these studies it became apparent that consumers in upper trophic levels could regulate populations of prey, and this regulation in turn had consequences for lower trophic levels as well as nutrient cycling. Manipulating consumer species as a means of removing algae or altering the uptake and storage of nutrients became an area of active study in order to manage lakes and improve water quality. These types of food web studies were also recognized as a means to monitor and to understand movements of toxic compounds such as DDT and mercury in lake ecosystems. Even very low concentrations of toxins in the open water can build up in sediments and bioaccumulate over time in upper trophic levels.

Studies of introduced predators by Robert Paine and Tom Zaret further emphasized that nonnative predatory species disrupted food webs. However, some ecologists argued that native predators rarely altered prey populations or shifted

species composition. Steve Carpenter and James Kitchell demonstrated experimentally that these species changes did occur in open-water food webs of temperate lakes. Certain fishes could selectively remove large-sized zooplankton grazers (as Brooks and Dodson had earlier demonstrated), resulting in increased biomass of phytoplankton and decreased levels of dissolved nutrients in a trophic cascade. In other lakes, additions of certain predatory fish species had major effects on phytoplankton growth and nutrient cycling through the predators' effects on grazers. Carpenter and Kitchell performed a series of whole-lake experiments to show that fish predation altered zooplankton species composition and size spectra. Shifts in sizes and types of zooplankton herbivores (and other invertebrate predatory species) in turn altered the phytoplankton community and its productivity. These trophic cascades have mostly been observed in aquatic ecosystems (Carpenter *et al.*, 2010). Recent studies, however, demonstrate top-down effects through four trophic levels in tropical forests and coastal marine ecosystems.

Many studies have demonstrated that bottom-up control by nutrients also influences the rate of energy flow in food webs. For many years, additions of nutrients were known to increase phytoplankton biomass and to alter species compositions of algae. Zooplankton abundances and species richness, in turn, often decline when the quality of their algal food resources is reduced. Thus, the distinct pathways of energy flow are altered by the amounts and proportions of nutrients available to algae and bacteria. High phosphorus concentrations lead to phytoplankton communities dominated by blue-green algae (cyanobacteria) because some species of blue-greens can fix nitrogen (incorporate it into their cells) from nitrogen gas in the atmosphere. Their capacity to use high amounts of both phosphorus and nitrogen allows them to outcompete the species of green algae and diatoms that cannot use atmospheric sources of nitrogen. Blue-greens can also take up and store nutrients internally beyond their metabolic needs for nutrients and deprive other species of recycled nutrients. Many species of blue-greens have distinct features (slime sheaths, toxins, and large sizes of colonies) that make them relatively unpalatable to many grazers. Some species of blue-greens produce toxic substances. By avoiding grazers, blue-green algal species can grow rapidly in the upper waters of lakes and ponds, thereby shading out the competing species. Blue-green algae often form long, chain-like colonies of cells that are less readily filtered by certain species of large zooplankton. Thus, zooplankton production often declines in waters dominated by blue-greens, and with fewer large zooplankton available as prey the production by fish predators also declines.

In many ecosystems a combination of top-down and bottom-up control can be expected. The roles of specific species in determining how nutrients are used and how rapidly energy flows through different food webs are being studied. The generality of these complex relationships and the predictability of patterns of food web responses to additions of nutrients or the additions or deletions of predators are not completely established. There are some traits that appear to increase the likelihood of certain patterns, and these are under intensive study. For example, as plants and animals die and sink into deep, density-stratified lakes the breakdown of organic matter releases nutrients that can accumulate and

dissolved oxygen can be depleted. Deoxygenation sets up chemical conditions in the sediments that release previously bound nutrients that are added to bottom waters. During mid- or late summer nutrients will be scarce in uppermost brightly lit waters (photic zone) in temperature-density stratified lakes because essential nutrients have become increasingly concentrated (during the spring and early summer growing season) in the lowest layers of water below the photic zone. With these accumulated nutrients stored seasonally in deep waters in which light is limited and nutrients cannot be taken up by plants, the roles of grazers and predators are less likely to control nutrient dynamics. Biomanipulation of consumer species may be more effective in shallow, frequently wind-mixed lakes and ponds.

Stressful Environments as Testing Grounds: Ecosystem Services and Biodiversity

In some ecosystems the number of producer and consumer species is relatively low because they are adapted to severe environments. Similar situations can occur on isolated islands or in deep caves or hot springs. Only a few species can tolerate the physiological stresses associated with very high or low temperatures or highly variable or extreme salinities, acidities, or nutrient concentrations. Such sites are useful for conducting field experiments because the low number of species can be studied in detail and manipulated over relatively brief periods.

Because of their distance from mainland sources of colonizing species, headwater streams on tropical islands contain a few abundant species of freshwater decapods (shrimp and crabs) and only a few species of other detritivores. Recent studies in streams on Caribbean islands illustrate how species differ in their effectiveness as leaf shredders. Furthermore, these studies show that different species form processing chains and interact to transform suspended organic detritus into benthic biomass that is retained within headwater food webs rather than being washed downstream or accumulating in deep pools.

Whole-pool experiments in the Luquillo Experimental Forest on the island of Puerto Rico were used to study rates of leaf litter processing. Leaves of *Cecropia schreveniana* were placed into pools that were cleared of other detritus. To start the experiments, either *Xiphocaris elongata* or *Atya lanipes* was placed into the treatment pools in which other detritivorous shrimp had been removed. Controls were pools with *Cecropia* but with no shrimp. Downstream concentrations of suspended fine, medium, and coarse particulate organic matter, dissolved organic carbon, total dissolved nitrogen, nitrate, and sulfate were measured during 23 days.

Results of the experiments illustrate how differently these two species function as detritivores. Both species of shrimp accelerated leaf breakdown rates relative to controls where only microbial decomposition occurred. *Xiphocaris* shredded *Cecropia* leaves much faster than *Atya*. *Xiphocaris* rapidly shredded the large, intact *Cecropia* leaves and converted them into fine suspended particulates. *Xiphocaris* increased the rate of downstream export of particulate organic matter and concentrations of total dissolved nitrogen and dissolved organic carbon relative to controls. These differences in processing rates also affected downstream distributions of suspended

particulate organics and nutrients. *Atya* increased rates of leaf breakdown less than did *Xiphocaris* and apparently filtered out fine organic particulates resulting in less downstream export. *Atya* are especially well adapted to shred conditioned leaves and to scrape microbes from leaf surfaces at low flows. *Atya* are also well adapted with highly modified cheliped fans to filter suspended organic particulates from the water when flow rates are higher than 20 cm s^{-1} . Although both of these shrimp are detritivores, they are not complete substitutes for each other. Their co-location and relative abundances affect rates of detrital processing when they form detrital processing chains.

Why Species Matter

Recent studies have demonstrated that some ecosystem processes apparently do change as the number of species increases. One of the most cited examples is the relationship between increased numbers of species in mixtures of annual plants that are grown in experimental plots. The total area of the plot covered by plant growth (an indirect measure of primary productivity) increased as the number of species increased from 1 to 24. The mechanisms for this relationship are not clear, but progress is being made in interpreting the effects of species composition on these and similar replicated experiments dealing with primary productivity.

Linking species to different ecosystem processes (such as productivity and decomposition) highlights the importance of how organisms interact. In some cases, these interactions may facilitate how rapidly processes occur. For example, decomposition of organic matter prevents buildup of organic detritus, which could lead to increased or reduced growth of macrophytes depending on the amounts and types of litter. In other cases the role of different benthic species in breaking down litter can prevent deoxygenation of lakes and streams and maintain supplies of clean water.

Future Studies

Given the rapid and accelerated loss of species and the irreversibility of global extinction, it is imperative that experimental and conceptual studies do more to examine multiple levels of ecological organization, from populations and communities to ecosystems and landscapes, before more species are lost. Unfortunately, we lack sufficient information about how the loss of different species can disrupt natural ecosystem services. These losses represent a type of "warning light" that should draw more attention to analyzing the consequences of losing native species and introducing nonnative species that may disrupt ecosystem dynamics. The increased dispersal of non-native, invasive species increasingly threatens the stability and sustainability of ecosystems. New technology for monitoring these changes in species distributions and their consequences are developing as part of the National Ecological Observatory Network (NEON). Airborne sensors are beginning to monitor the rates of changes in vegetation across landscapes in response to climate changes, outbreaks of pathogens, and expansions of invasive species.

Improved techniques using stable isotopes, enhanced computer models, and many other developments have expanded the means of addressing ecosystem questions. However, only recently have ecologists evaluated the importance of species-specific attributes in ecosystem processes. Part of the reason for this slowness is that complete food webs are complex and dynamic. Furthermore, the specific functions of a single species are difficult to isolate from the functions of other species in most natural communities. Probably the most important factor has been the development of different scientific perspectives by population ecologists, community ecologists, and ecosystem ecologists. The recent emphasis on integration across subdisciplines has created a new perspective on the importance of different species' roles in performing different ecosystems "services" or essential functions for society, such as nutrient cycling and productivity.

Environmental Ethics

Philip J Cafaro, Colorado State University, Fort Collins, CO, USA

Richard B Primack, Boston University, Boston, MA, USA

Published by Elsevier Inc.

Glossary

Anthropocentrism Position that only human beings have moral worth or intrinsic value.

Biocentrism Position that all living beings have moral worth or intrinsic value.

Deep ecology Activist philosophy that advocates radical personal and political change to protect wild nature.

Environmental ethics Philosophical discipline that specifies proper human relationships to the natural world.

Ethical holism Position that complex aggregates, such as species, ecosystems, or human groups have intrinsic value.

Humanism Environmental philosophy devoted to maximizing human wealth, flourishing, power, and numbers.

Instrumental value Value of something relative to human interests or desires.

Intrinsic value Value of something independent of its value to people.

Rights Justified claims that people respect a being's existence and important interests, and act accordingly.

Stewardship God-given responsibility to protect natural resources and preserve biological diversity.

Duties to Protect Biodiversity: Intrinsic Value Arguments

From Economics to Ethics

Biodiversity has high economic value, both direct and indirect. Direct economic values are provided by wild game, seafood, fuelwood and timber products, and indigenous and high-technology medicines. Indirect economic values accrue from biodiversity's roles in waste disposal, climate regulation, building soil and purifying water, recreation and tourism, and much more. Both directly and indirectly biodiversity safeguards or adds to human wealth, often justifying its protection in purely economic terms.

Thus, economic arguments by themselves provide a basis for valuing and protecting species, especially when we expand our concept of economic value from short-term, next-quarter profits to include longer term and indirect benefits. But economic arguments can also provide grounds for extinguishing species or for saving one species rather than another (Czech, 2002). Halting profitable developments or making costly attempts to preserve species may not have any obvious economic justification, while in some circumstances, economic justification could exist for destroying an endangered species, particularly organisms that cause disease, attack crop plants, or simply get in our way. Still, many people believe that such destruction is morally wrong even if it is economically profitable.

To say that an object has economic value is to say that it is useful to human beings or that they desire to possess it. In other words, it has an instrumental value: one can use it for his or her purposes. However, we recognize that at least some entities have value regardless of whether anyone else values or uses them. These entities have an intrinsic value: a value that is grounded not in their usefulness to others, but in what they are themselves.

Human beings, we usually think, have intrinsic value, and therefore possess certain rights that no one can legitimately infringe. Conversely, we have certain duties toward other

people that specify how we should treat them in various situations. We cannot help but look at the people we interact with each day in terms of their usefulness to us, but if we look at them solely in these terms we disrespect their (and our) humanity and if we treat them solely as a means to our own ends we are likely to behave immorally.

Many conservationists argue that similar duties restrict the morally acceptable treatment of wild nature (Leopold, 1987). They consider it wrong to destroy a rare woodland or cause a species to go extinct, even if this action is in an individual's or corporation's self-interest. Not only do we not have any right to destroy species, we also have a moral responsibility to actively protect species from extinction as the result of our activities. Opponents counter that this position is illegitimate because only human beings have intrinsic value. Unless our actions affect other people, directly or indirectly, any treatment of the natural world is morally acceptable.

Extensionist Arguments for Intrinsic Value

Proponents provide both extensionist and nonextensionist arguments for the intrinsic value of wild nature (Agar, 2001). Extensionist arguments ask what qualities give intrinsic value to human beings, and then assert that some other beings possess these same qualities. Therefore, they conclude, we should recognize the intrinsic value of these other beings and extend proper treatment to them.

One common justification for valuing human beings is our ability to reason. But some of the so-called higher animals also seem to possess the rudiments of reason. Chimpanzees and gorillas have been taught sign language involving several hundred words; wolves have an elaborate social life and the ability to coordinate long hunts; and dolphins, whales, and other cetaceans send complex signals that we are just beginning to understand. Many argue that because of these factors, we should not hunt these animals for food or sport, use them in research, or in general treat them solely as means to our own ends.

Other philosophers believe that sentience – the ability to perceive the surrounding world and feel pleasure and pain – demands moral consideration. The extensionist argument here states that because pain is bad we should avoid inflicting pain unnecessarily on others who can feel it – even if those others have fur, feathers, scales, or numerous legs. Immoral actions against human beings are wrong, at base, because they cause unnecessary suffering; actions that cause other animals unnecessary suffering are likewise immoral. Millions of people around the world act on such beliefs by abstaining from eating animals or using products that can only be procured by killing or harming them. Once they have visited a modern concentrated animal feeding operation (CAFO), even most meat-eaters recognize that these animal factories are immoral, because they inflict gross, unnecessary suffering on the animals. This suggests a widespread belief that where there is sentience there exists some moral responsibility.

One possible problem with the extensionist arguments just discussed, from the point of view of conservationists, is that they only encompass certain organisms (Rolston, 1989). Basing intrinsic value on some rudimentary form of reasoning or complex mental experience would appear to rule out most animals; for example, almost all invertebrate species. Basing moral consideration on the ability to feel pain includes a wider class of animals, but again many simpler animals and all the other kingdoms of life are ruled out.

However, extensionist arguments can be extended further by recognizing that all organisms have a drive to stay alive and reproduce. In the same way that we acknowledge the rights of people to live, have children, and satisfy basic needs, we may extend these rights to individuals of all species. In his autobiography, Albert Schweitzer maintained that “a man is ethical only when life, as such, is sacred to him, that of plants and animals as that of his fellow men, and when he devotes himself helpfully to all life that is in need of help.”

This position may lead to a very demanding code of conduct! Believers in strict biocentric equality assert that it is always wrong to kill individuals of any species (because of their intrinsic value) unless we need to do so to survive. Others believe that using nature to provide necessities and some measure of comfort is morally acceptable, but not to provide luxury goods. On this view, cutting down trees for firewood or to build a modest house is morally acceptable, particularly if this is done sustainably, whereas harvesting mahogany trees from rain forests to make expensive furniture for wealthy individuals half a world away is morally unacceptable. Whatever the particular judgments made, recognition of an intrinsically valuable organic world leads to distinctions between essential and inessential human uses and to a more limited, respectful use of natural resources.

Nonextensionist Arguments for Intrinsic Value

In addition to extensionist arguments, which point out similarities between wild nature and intrinsically valuable humans, there are arguments that find value in nature without referring to such similarities. Some believe it is a mistake to value other beings only for the ways in which they resemble humans. Robert Elliot in *The Monist* (1992) suggested that

natural organisms may have the following properties that give them intrinsic value: “diversity, stability, complexity, beauty, harmony, creativity, organization, intricacy, elegance, and richness.” These are qualities of natural organisms that we can appreciate – and that may call forth responses of personal restraint and active protection.

All species represent unique biological solutions to the problem of survival. They have solved the challenges placed before them by their environments and thrived. Some people see a value in this creativity and time-tested uniqueness. Others appreciate the beauty and elegance of the forms created by these natural processes. Still others value the complexity and ingenious structures that science and close observation have revealed. People who know and value this uniqueness, beauty, and complexity feel a special horror at its permanent disappearance. After all, if an individual dies it may be replaced by another individual more or less the same, but take away the last passenger pigeon or giant moa and their like will never return. Nonextensionist arguments thus support preservation of species, as well as protection of individual organisms (*see Ethical Holism*).

While philosophers debate whether it makes sense to assign rights to species, conservation activists are working to make such rights a legal reality. Arguably, the US Endangered Species Act, passed in 1973, created a *de facto* species right to continued existence, free from untimely human-caused extinction. In 2008, the people of Ecuador went further, explicitly adding a new chapter on the rights of nature to their national constitution. The additions, proposed by a constitutional convention and ratified by popular vote, included the following:

Article 1. Nature or *Pachamama*, where life is reproduced and exists, has the right to exist, persist, maintain itself, and regenerate its own vital cycles, structure, functions, and its evolutionary processes.

Article 3. The State will motivate natural and juridical persons as well as collectives to protect nature; it will promote respect towards all the elements that form an ecosystem.

Article 4. The State will apply precaution and restriction measures in all the activities that can lead to the extinction of species, the destruction of the ecosystems or the permanent alteration of natural cycles.

While individual human beings remain our paradigm rights-holders, societies have wide latitude to create novel rights for larger wholes. For example, the United Nations Convention on the Prevention and Punishment of the Crime of Genocide, adopted in 1948, established a right against efforts to extinguish racial or ethnic groups. Such human group rights are no different in principle from nonhuman species rights. The key question is whether the creation of such rights furthers justice and the common good.

Human maturity leads naturally to self-restraint and a respect for others. Many conservationists agree with Arne Naess (1989), who writes that the further maturation of the human species will involve an “identification with all life forms” and “the acknowledgment of the intrinsic value of these forms” in an expanding circle of moral obligations. Moving outward from oneself, the circle would include duties to our family and relatives, our local community, our country, all humanity,

mammals (Save the Whales!), all animals (Save the Snail Darter!), all species (Save the Yellow Lady Slipper Orchid!), ecosystems (Save the Rain Forest!), and ultimately the whole Earth (Figure 1). Such an expansion of ethical concern involves new limitations on acceptable actions, but also new opportunities for personal growth and flourishing.

Anthropocentric Denials of Intrinsic Value

Skeptics believe that even though some people do value nonhuman organisms and species, we are not obligated to do so, because only human beings have intrinsic value or possess genuine rights (Ferry, 1995). Humans have a value beyond all other beings because only we are fully conscious and rational. Unless our actions affect other people, directly or indirectly, any treatment of the natural world is morally acceptable.

Such a viewpoint is anthropocentric – locating intrinsic value solely in humans – and to many it seems the most obvious common sense, while departures from it seem irrational or overly sentimental. The appellation “tree hugger” well expresses this view, suggesting inappropriate sentiments toward trees, leading to inappropriate actions. It also suggests a callous disregard for the interests of people, like those who cut trees for a living, who we really should care about. Consider the bumper sticker “Hug a Logger, Not a Tree.” People who value nature counter that anthropocentrism is selfish and that speciesism – the privileged treatment of one species over another – is no more justified than racism or sexism.

Another argument against nature’s intrinsic value is that recognizing it leads to absurdity. Even people who appreciate wild nature often resist granting it intrinsic value, since this seems to demand so much from us. If nature is wonderful and complex, as science and our own experiences tell us it is, how can we go on using it? But we must do so to survive. Besides,

the world is already filled with rules limiting our actions; adding even more would be burdensome. Finally, since our modern lifestyles depend to a large extent on an ecologically destructive economic system, many despair of protecting the world and give up trying to live in an environmentally responsible manner.

These are legitimate concerns. Still, effective action to protect biological diversity is both possible and desirable. First, it is possible to use natural resources in a respectful and limited way: It is necessary to use nature, but not all uses of nature are necessary. Second, while no one likes more rules, growing up and living moral lives involves recognizing our duty to others. If nature does in fact have intrinsic value, we should respect that value – whether doing so is convenient or not. Opponents of this view counter that even though some people do value certain qualities in wild nature, they are not morally required to do so. And they repeat that humans have a value beyond all other species’ value, because only we are fully conscious, rational, and free beings.

Although the debate between anthropocentrists and biocentrists has tended to incorporate all the uncertainties attending ethical justification in general, some clarification has still resulted. Charges of irrationalism to the contrary, it is possible to love and value nonhuman nature and to act on this view. The challenge for biocentrists is to fashion good lives that limit their negative environmental impacts and help preserve and celebrate nature (Mills, 2003). Anthropocentrism also remains a rationally defensible position, which may be consistently acted on. Anyone who values humanity based on qualities that we share with other species, however, cannot consistently deny intrinsic value to those other species. Furthermore, anthropocentrists who value humanity primarily for our ability to reason may consider the many arguments in favor of lessening pollution and preserving wild nature that appeal to our rational self-interest (see Biodiversity and Human Flourishing). Anthropocentrists are more likely than biocentrists to accept some amount of pollution in rivers or the extinction of certain species, but they also acknowledge human needs for clean air and drinking water, the enjoyment we get from fishing, swimming, and canoeing, and the value of biodiversity to science, art, and business. When it comes to particular environmental policies, anthropocentrists and biocentrists may find considerable common ground (Norton, 2003).

Ethical Holism

The preservation of biodiversity seems to demand that the needs of endangered species take precedence over the needs of individual organisms. For example, the US National Park Service killed hundreds of introduced rabbits on Santa Barbara Island off the California coast to protect a few plants of the endangered Santa Barbara live-forever (*Dudleya traskiae*) (Figure 2). In this case, one endangered species was judged to be more valuable than hundreds of individual animals of a common species (Rolston, 1994). Similarly, conservation biologists would not find it acceptable to destroy the last remnant of a rare biological community even if every species living there could be maintained in captivity; the ecological

Figure 2 Beasts vs the biosphere. Government agencies judged the continued existence of the endangered plant Santa Barbara live-forever (*Dudleya traskiae*; the tall plant in the photo) to be more valuable than the common rabbits on its island home. The rabbits, which fed on the plant's fleshy leaves (shown at the bottom right), were killed to stop their destruction of this fragile plant species. Reproduce with permission from National Park Service photograph.

interactions and evolutionary processes of the community would be lost if the species only lived in captivity. These examples illustrate that most conservationists are holists, finding value in larger groupings, such as species and biological communities. They are thus sometimes willing to sacrifice the interests of individuals to preserve species and communities.

Many writers, especially animal welfare advocates, have difficulty assigning rights to species. Peter Singer and Tom Regan, two prominent philosophical animal rights advocates, argue that species are not conscious entities and so do not have interests. In their view, to sacrifice the genuine interests of an individual animal to the imagined interests of a species is mistaken. Many animal welfare advocates also reject conservationists' special concern for native species over exotics: an animal is an animal, with a greater or lesser ability to suffer, and this should determine our behavior toward it, rather than its point of origin.

On both biological and ethical grounds, however, most conservation biologists argue that species, rather than individual organisms, are the appropriate targets of conservation efforts. All individuals eventually die; it is the species that continues,

Figure 3 Unwelcome guests. The Zebra mussel (*Dreissena polymorpha*), a native of the Caspian Sea, was accidentally introduced into the Great Lakes and associated rivers in 1988. Since then the species has formed dense populations over a wide and ever-increasing area, outcompeting and choking out native species. In this case, thumb-sized Zebra mussels have almost totally encrusted a crayfish shell. Photograph courtesy of Ontario Ministry of Natural Resources from the Great Lakes Sea Grant Exotic Species Library.

evolves, and sometimes forms new species. In a sense, individuals are temporary representatives of species. Whether or not we allow them rights, species carry high value as the repositories of the accumulated experience and history of millions of previous life forms through their continuous, evolutionary adaptation to changing environments. The premature extinction of a species due to human activities destroys this natural process and obliterates its history. It can be regarded as a "superkilling" because it kills future generations of the species and eliminates whole lines from the processes of evolution and speciation.

Furthermore, conservationists typically argue that species should be prevented from spreading beyond their natural ranges as a result of direct or indirect human activity. For example, the zebra mussel (*Dreissena polymorpha*) is native to the Caspian Sea, but it has recently become an aggressive invader of North American aquatic habitats (Figure 3). Arguably this species should be destroyed whenever possible in North America, for two reasons. First, exotics often displace native species, sometimes contributing to their extinction. To prevent this loss of biological diversity we destroy individual exotics, on the assumption that the exotic species will continue to thrive in its native habitats. Second, and more controversially, many conservationists deny intrinsic value to individual plants and animals that have been spread beyond their natural range by people. Part of what gives a species value is its unique evolutionary history and its ecological roles in native habitats, both of which are tied to particular places and biological communities. When these species instead invade new natural areas and destabilize or radically change their species composition, these justifications of their value no longer hold. Species contribute to biodiversity in their native habitats but often diminish biodiversity when they become common in exotic new locales. If our overarching conservation goal is to protect life's full flourishing and diversity, exotic species are immensely harmful and should be reined in where practical.

Duties to Protect Biodiversity: Obligations to People and to God

Duties to Humans

That human beings have direct moral duties to other species remains controversial; that we have direct moral duties to other human beings is not (although great disagreement remains regarding their scope). Our duties to other human beings may support environmental protection and biodiversity preservation, based on their instrumental value to intrinsically valuable people (Moore and Nelson, 2010).

We have responsibilities toward our neighbors and fellow citizens. Because of this, we must arguably minimize damage to the natural environment, since such damage harms not only other species but people as well. Increasingly, connections are being made between environmental pollution and high levels of human disease. For example, massive environmental pollution in the former Soviet Union greatly increased cancer, birth defects, lead poisoning, and lung disease among the population. In the United States, evidence is growing that increased levels of endocrine-disrupting chemicals are harming people as well as wildlife. Much pollution and environmental degradation is unnecessary and could be minimized with better planning. Often pollution occurs because corporate leaders are unwilling to spend money to prevent it, despite the resulting ill effects on the health, wealth, or happiness of other people. Citizens must recognize the biological and social costs of environmental damage and force corporations to be good neighbors and governments to enact and enforce strong environmental laws for the common good.

We also have responsibilities toward future generations. Economic decision making tends to focus on the short term and it is this economic system that is driving environmental degradation (Speth, 2009). In response, many ethicists have emphasized the importance of intergenerational justice (Gardiner *et al.*, 2010). Humanity's unprecedented numbers and technological power mean that one generation can now radically remake the Earth that the next will inhabit, for better or worse. If in our daily living we degrade the natural resources of the Earth and cause species to become extinct, future generations will pay the price in terms of a lower quality of life.

This truth gives us arguments not just for keeping ecosystems unpolluted to safeguard human health, but also for preserving biodiversity for future human use, enjoyment, and development. If species and wild places are lost, children will be deprived of one of their most exciting experiences growing up – the wonder of seeing “new” animals and plants in the wild. These concerns are a powerful motivating force for the members of organizations such as the Sierra Club and the Nature Conservancy, who see themselves as land stewards preserving biodiversity for future generations. Over one hundred and fifty years ago, reflecting on the depauperate ecological landscape around him in Concord, Massachusetts, Henry Thoreau wrote in his journal:

“When I consider that the nobler animals have been exterminated here, I cannot but feel as if I lived in a tamed, and, as it were, emasculated country ... I take infinite pains to know the phenomena of the spring, thinking that I have here the entire poem, and then, to my chagrin, I hear that it is but an imperfect copy that I

possess and have read, that my ancestors have torn out many of the first leaves and grandest passages, and mutilated it in many places.” (March 23, 1856).

Like Thoreau, many of us believe that our descendants will “wish to know an entire heaven and an entire Earth.” They have a right to know and explore wild nature. We should not take that away from them.

Holmes Rolston in the *Encyclopedia of Environmental Biology* (1995) predicted: “It is safe to say that in the decades ahead, the quality of life will decline in proportion to the loss of biotic diversity, though it is often thought that one must sacrifice biotic diversity to improve human life.” Of course, this contention is debatable. Many argue that creating jobs or increasing wealth is more important to future generations than the preservation of biodiversity (Lomborg, 2010). Debate on this issue, while inconclusive, is essential, because it forces us to specify the actual, long-term benefits of development projects and the sorts of societies we want to create for our children. Given our unprecedented power and the tendency to put personal interests above the common good, even inconclusive debate may be a force for creating a better future for all.

At a minimum, our duties to posterity seem to require us to live sustainably – that is, to limit our consumption so as not to degrade essential life-support systems or deplete natural resources that future generations will need. The world's governments have formally recognized this through treaties governing air pollution, whale hunting, disposal of wastes in the ocean, and more. One important treaty, the Montreal Protocol of 1987, reduced the permitted use of ozone-depleting chlorofluorocarbons (CFCs), leading to a gradual phaseout of production. The grave dangers these chemicals posed to future generations, with their potential to thin the Earth's protective ozone layer and cause millions of new cases of deadly skin cancer, clearly outweighed the interests of producers and users of CFCs, especially since many of these uses were not essential to human survival (e.g., luxury items such as hairsprays and air conditioners) and alternatives were available or quickly developed for most uses. Similar appeals to the good of future generations have so far proved less successful in convincing the world community to reduce fossil fuel use to slow global climate change. This is partly due to well-financed lobbying by oil and coal corporations, whose leaders have placed short-term profits above the health and well-being of future generations. Partly though it is because the risks of increased fossil fuel use, though grave, are somewhat uncertain, while the inconvenience and economic costs of decreasing fossil fuel use are far higher than they were for cutting back on CFCs. Nevertheless, it seems immoral for this current, wealthy generation of human beings to avoid serious action to combat global warming, when our inaction risks the lives and livelihoods of fellow human beings at home and abroad (Arnold, 2011).

Some people worry that preserving nature requires taking resources and opportunities away from human beings. Sometimes it does. But protecting biological diversity also can be linked to better health and greater opportunities for people (Cafaro and Sandler, 2010) and some of the most exciting developments in conservation biology attempt to do just that. Helping poor people establish sustainable plots of cash crops

and achieve a degree of economic independence may reduce the need to overharvest wild species. Working with indigenous people to secure legal title to their land may give them the means to protect the biological communities in which they live (although they do not always choose to do so in practice). Working to benefit people is often not just compatible with effective conservation, but necessary to its success.

Conservationists need to look for “win win” scenarios where the interests of people and nature can both be furthered, whether we are working in underdeveloped or overdeveloped nations. However, in some situations, protecting biological diversity will be incompatible with meeting immediate human needs or promoting short-term human interests. In such situations, hard choices will need to be made and these choices should not automatically favor people over other species, or current over future generations. Extinction is forever and extinguishing other species is rarely if ever necessary to preserve human lives. Our duties to future human generations arguably include a strong duty to preserve other species from extinction.

Religious Stewardship

Some preindustrial cultures successfully coexisted with a rich local flora and fauna for hundreds of years, in part because their religious and ethical beliefs encouraged the thoughtful use of resources. People in these societies respected wild animals and plants, even as they harvested them or borrowed their habitat for human purposes. For example, the Cherokee Indians of the southeastern United States spoke special prayers to the deer that they killed, telling the deer spirit that they indeed needed the meat, that they would not waste it, and that they would bury the bones with due solemnity. Traditional peoples often treated rivers, mountains and other ecosystems as sacred places to be approached with reverence and an appreciation for what they were, rather than with haste, focused on what human beings could make of them.

Many modern religious believers abhor the destruction of species, because they are God’s creation. Within the Jewish and Christian traditions, human responsibility for protecting animal species is explicitly described in the Bible as part of a covenant with God. The Book of Genesis describes the creation of the Earth’s biological diversity as a divine act, after which “God saw that it was good” and “blessed them.” In the story of Noah’s Ark, God commanded Noah to save two of all species – not just the ones human beings found useful. God provided detailed instructions for building the ark – an early species rescue project – saying “Keep them alive with you,” and after the flood subsided, the animals were released to repopulate the Earth. The prophet Mohammed, founder of Islam, continued this theme of human responsibility, saying “The world is green and beautiful and God has appointed you as His stewards over it. He sees how you acquit yourselves.”

Belief in the value of God’s creation supports a stewardship argument for preserving biodiversity: Human beings have been given responsibility for God’s creation and must preserve, not destroy, what they have been given.

Many other religious traditions also support the preservation of nature. For example, Hinduism locates divinity in

certain animals, and recognizes a basic kinship between humans and other beings (including the transmigration of souls from one species to another). A primary ethical concept in Hinduism, Jainism, and Buddhism is *ahimsa*: nonviolence, or compassion for all life. To live by this ideal, many believers become vegetarians and live materially simple lives.

Of course, some religions articulate views that put human beings at the center of creation, supporting a domineering attitude toward nature. But such interpretations are contested. Since many people base their ethical values on a religious faith, the development of religious arguments in support of conservation might be effective in motivating people to conserve biodiversity (Wirzba, 2003).

In September 1986, an interfaith ceremony was held in the Basilica of St. Francis, in Assisi, Italy. It included “Declarations on Nature” by representatives of the five participating religions: Buddhism, Christianity, Hinduism, Islam, and Judaism. For the first time in history, leaders of these faiths came together to declare that their religions mandate the conservation of nature. Excerpts from the five declarations follow.

The Buddhist Declaration on Nature

Venerable Lungrig Namgyal Rinpoche, Abbot, Gyuto Tantric University

The simple underlying reason why beings other than humans need to be taken into account is that, like human beings, they too are sensitive to happiness and suffering Many have held up usefulness to human beings as the sole criterion for the evaluation of an animal’s life. On closer examination, one discovers that this mode of evaluation of another’s life and right to existence has also been largely responsible for human indifference as well as cruelty to animals.

We regard our survival as an undeniable right. As coinhabitants of this planet, other species too have this right for survival. And since human beings as well as other nonhuman sentient beings depend on the environment as the ultimate source of life and well-being, let us share the conviction that the conservation of the environment, the rectification of the imbalance caused by our negligence in the past, be implemented with courage and determination.

“All sentient beings, all breathing things, creatures without exception, may no evil befall them.” – Gradual sayings of the Buddha.

The Christian Declaration on Nature

Father Lanfranco Serrini, Minister General, Order of Friars Minor (Franciscans)

To praise the Lord for his creation is to confess that God the Father made all things visible and invisible; it is to thank him for the many gifts he bestows on all his children By reason of its created origin, each creature according to its species and all together in the harmonious unity of the universe manifest God’s infinite truth and beauty, love and goodness, wisdom and majesty, glory and power.

Man’s dominion cannot be understood as license to abuse, spoil, squander, or destroy what God has made to manifest his glory. That dominion cannot be anything other than a stewardship in symbiosis with all creatures Every human act of

irresponsibility toward creatures is an abomination. According to its gravity, it is an offense against that divine wisdom which sustains and gives purpose to the interdependent harmony of the universe.

The Hindu Declaration on Nature

Dr Karan Singh, President, Hindu Virat Samaj

The Hindu viewpoint on nature is permeated by a reverence for life, and an awareness that the great forces of nature – the earth, the sky, the air, the water and fire – as well as various orders of life including plants and trees, forests and animals, are all bound to each other within the great rhythms of nature. The divine is not exterior to creation, but expresses itself through natural phenomena. The *Mahabharata* says that ‘even if there is only one tree full of flowers and fruits in a village, that place becomes worthy of worship and respect’.

Let us declare our determination to halt the present slide toward destruction, to rediscover the ancient tradition of reverence for all life and, even at this late hour, to reverse the suicidal course on which we have embarked. Let us recall the ancient Hindu dictum: “The Earth is our mother, and we are all her children.”

The Muslim Declaration on Nature

Dr Abdullah Omar Nasseef, Secretary General, Muslim World League

The essence of Islamic teaching is that the entire universe is God’s creation. Allah makes the waters flow on the earth, upholds the heavens, makes the rain fall and keeps the boundaries between day and night It is God who created the plants and the animals in their pairs and gave them the means to multiply.

For the Muslim mankind’s role on earth is that of a *khalifa*, viceregent or trustee of God. We are God’s stewards and agents on Earth. We are not masters of this Earth; it does not belong to us to do what we wish. It belongs to God and He has entrusted us with its safekeeping The *khalifa* is answerable for his/her actions, for the way in which he/she uses or abuses the trust of God.

The Jewish Declaration on Nature

Rabbi Arthur Hertzberg, Vice President, World Jewish Congress

The encounter of God and man in nature is conceived in Judaism as a seamless web with man as the leader and custodian of the natural world ... Now, when the whole world is in peril, when the environment is in danger of being poisoned and various species, both plant and animal, are becoming extinct, it is our Jewish responsibility to put the defense of the whole of nature at the very center of our concern.

We have a responsibility to life, to defend it everywhere, not only against our own sins but also against those of others. We are all passengers together in this same fragile and glorious world. Let us safeguard our rowboat – and let us row together.

“... and the rainbow shall be in the cloud; and I will look upon it, that I may remember the everlasting covenant between God and every living creature ... that is upon the Earth.” – Genesis 9:16

Biodiversity and Human Flourishing

Economic arguments stress that preserving biological diversity is in our material self-interest. Ethical arguments based on the intrinsic value of wild nature and our duties to others stress that we should act altruistically toward nature regardless of our material self-interest. A second ethical framework appeals

to our enlightened self-interest, arguing that preserving biodiversity and developing our knowledge of it will make us better and happier people (Sandler, 2007). Protecting biological diversity is in our enlightened self-interest, for the following reasons.

Esthetic and Recreational Enjoyment. Nearly everyone enjoys wildlife and landscapes esthetically, and joy increases the quality of our lives. Nature-related activities are important in childhood development. The beauty of a field of wildflowers in Glacier National Park or a migrating warbler on a spring morning in a city park enriches people’s lives (Thoreau, 1971). And for many people, truly experiencing nature means experiencing it in a natural setting – simply reading about species or seeing them in museums, gardens, or zoos does not suffice (Figure 4). Recreational activities such as hiking, canoeing, and mountain climbing are physically, intellectually, and emotionally satisfying. People spend tens of billions of dollars annually in these pursuits, proof enough that they value them highly.

Artistic Expression and Philosophical Insight. Throughout history, writers, artists, and musicians of all cultures have drawn inspiration from wild nature. Nature provides countless forms and symbols for painters and sculptors to render and interpret (Figure 5). Poets have often found their greatest inspiration in either wild nature or the pastoral countryside. Preserving biological diversity preserves possibilities for all artists and for everyone who appreciates their works. Philosophers too go to nature to find insights into human existence and our place in the wider universe. A loss of biodiversity limits such experiences and diminishes our intellectual resources. It is hard to see how, in a world without mockingbirds, Americans could appreciate Walt Whitman’s “Out of the Cradle Endlessly Rocking,” one of their greatest poet’s greatest poems. And it is sad to think what other poems, songs, stories, or pictures will remain unsung, untold, or unmade, in a world without butterflies or broad meadows filled with wildflowers.

Figure 4 Reaching out. Most people find interacting with other species to be an educational and uplifting experience. Here, people greet a minke whale that is being rescued after it became entangled in a trawler’s gill net; the float behind the whale was attached to the net to keep the whale at the surface so that it could breathe. Later, rescuers were able to release the whale from the netting. Reproduced with permission from Scott Kraus, New England Aquarium.

Figure 5 Celebrating nature. Rare wildflowers and butterflies are the inspiration for botanical sculptor Patrick O'Hara. In his studio in western Ireland, O'Hara molds, sculpts, and paints delicate porcelain scenes from nature that inspire an appreciation of biodiversity in a worldwide audience. Photograph courtesy of O'Hara (2006).

Scientific Knowledge. Science and our growing knowledge of nature are among humanity's greatest achievements. This knowledge is facilitated by the preservation of wild nature. Wild areas allow the study of natural ecological processes and interactions. Wild species preserve the record of evolution. Young people are inspired to become scientists by personal contacts with wild nature, and those who do not become professional scientists can apply their basic knowledge of science to understanding their own local forests, streams, and fields.

Three of the central mysteries in the world of science are how life originated, how the diversity of life interacts to form complex ecosystems, and how humans evolved. Biologists working on these problems are coming ever closer to the answers. However, when species become extinct and ecosystems are damaged, important clues are lost, and the mysteries become harder to solve. For example, if *Homo sapiens'* closest living relatives – chimpanzees, bonobos, gorillas, and orangutans – disappear from the wild, we will lose important clues regarding human physical and social evolution.

Historical Understanding. Knowing nature, both scientifically and through personal experience, is key to an understanding of human history. In walking the landscapes our ancestors walked, we gain insight into how they experienced the world at a slower pace and without mechanized aids. We often forget just how recently humankind has moved to ultrafast transportation, fully illuminated cities that shut out the night, and other aspects of modern life. We need to preserve natural areas in order to develop our historical imaginations and preserve ties to our past (Leopold, 1987).

Religious Inspiration. Many religions have traditions of “wandering in the wilderness” in order to commune with God or with spirits, or to purify themselves of the temptations and evils associated with life within human communities. Moses, Isaiah, St. John the Baptist, St. Francis of Assisi, and Jesus all sought out the solitude of wilderness to obtain spiritual strength and receive the guidance of God. Generations of Sioux, Ute, Cheyenne, and other Native American vision seekers have done the same. Being in nature allows us to clear and focus our minds and sometimes, experience the transcendent. When we are surrounded by the artifacts of civilization, our minds usually stay fully focused on human purposes and our everyday lives. Religion probably would not disappear from an environment totally tamed by humans, but it might become diluted for many.

Protecting our Life-Support Systems and Economies. It cannot be repeated too often that biological diversity preserves our basic life-support systems of food production, water supply, oxygen replenishment, waste disposal, soil production, and more. People will be healthier and happier in clean, intact environments. We depend on this and should value it. In addition to providing life-support, biodiversity allows us to create tremendous economic wealth, directly and indirectly. An article published in *Nature* in 1997 by Robert Costanza *et al.* “The Value of the World’s Ecosystem Services and Natural Capital,” estimated that the world’s ecosystems provided \$32 trillion per year of value to people, substantially higher than the \$18 trillion per year of goods and services those people produced themselves. Human society could not exist without what the natural world provides us with for free, nor could we afford to pay for substitutes, even if they existed.

For all these reasons, degrading ecosystems and destroying species is almost always contrary to people’s real interests. When it appears otherwise, that is usually because we are taking a short-term, selfish, or overly materialistic view of what those interests are (Norton, 2003). While the preservation of biodiversity sets limits to some human activities, it is a prerequisite for our continued enjoyment of others. There are good reasons to believe that preserving and exploring biodiversity can make us better, happier people (Cafaro and Sandler, 2010). Many environmental ethicists are convinced that a better understanding of our true self-interest would lead to greater efforts to protect biological diversity.

Environmental Philosophies

Deep Ecology

Recognition of the many instrumental and intrinsic values of biological diversity leads naturally to new limits on human action. This can make it seem like conservation is simply a never-ending list of “thou shalt nots.” But this is only part of the story, and many environmentalists come to a different conclusion. According to Arne Naess (1989): “The crisis of life conditions on Earth could help us choose a new path with new criteria for progress, efficiency, and rational action... The ideological change is mainly that of appreciating life quality rather than adhering to a high standard of living.”

One well-developed environmental philosophy that embraces this new approach to living in nature is known as deep ecology (Naess, 2008). It builds on the basic premise of biocentric equality: that all creatures have an equal right to live and thrive in their own ways. Proponents oppose what they see as the dominant worldview, which places human concerns above all others and views human happiness in materialistic terms (Table 1).

Deep ecologists may hold various foundational beliefs. Some are Christians, Jews, or Buddhists, while others are agnostics or atheists; philosophically, they may be utilitarians, communitarians, or rights-theorists, or they may have no well-worked-out theory of ethics. What they have in common is a belief in wild nature's great value and a strong commitment to act to preserve it. This belief and commitment are captured in the eight-point Deep Ecology Platform, formulated by Arne Naess and George Sessions:

1. The well-being and flourishing of human and nonhuman life on Earth have value in themselves (synonyms: inherent worth, intrinsic value, inherent value). These values are independent of the usefulness of the nonhuman world for human purposes.
2. Richness and diversity of life forms contribute to the realization of these values and are also values in themselves.
3. Humans have no right to reduce this richness and diversity except to satisfy vital needs.
4. Present human interference with the nonhuman world is excessive, and the situation is rapidly worsening.
5. The flourishing of human life and cultures is compatible with a substantial decrease of the human population. The flourishing of nonhuman life requires such a decrease.
6. Policies must therefore be changed. The changes in policies affect basic economic, technological, and ideological structures. The resulting state of affairs will be deeply different from the present.
7. The ideological change is mainly that of appreciating life quality (dwelling in situations of inherent worth) rather

than adhering to an increasingly higher standard of living. There will be a profound awareness of the difference between big and great.

8. Those who subscribe to the foregoing points have an obligation directly or indirectly to participate in the attempt to implement the necessary changes (Naess, 1989).

Deep ecologists and other biocentric philosophers see acceptance of the intrinsic value of nature less as a limitation than as an opportunity to live better lives. Over the past 200 years, the Industrial Revolution, with its accompanying technological advances and social changes, has generated tremendous material wealth and improved the lives of millions of people. But a law of diminishing returns seems to apply: for many people throughout the world, heaping up further wealth makes little sense, while the continued loss of biodiversity and taming of natural landscapes will not improve their lives (McKibben, 2007). What is being lost is unique and increasingly more precious as wealth increases and opportunities to experience wild nature diminish. These radical environmental philosophies thus ask us to imagine creating new sorts of economies that provide a sufficiency of goods and services for a limited number of people, not ever-increasing amounts of goods and services for endlessly more people.

Some biocentric philosophers also ask us to imagine different kinds of people living and working within these economies – if only because we will have to be somewhat different in order to accept living within limits. The kind of selfish, shortsighted behavior that is destroying biodiversity today will not change because of a few good arguments, or even solely because of new laws and institutions – although new laws and institutional change are certainly needed. Put bluntly, the claim is that in order to preserve biodiversity, we are going to have to become *better people* than we are right now.

Virtue ethics is the area of philosophy focused on ideals of human excellence. Virtue ethicists work to specify those qualities of human character (“the virtues”) that make people *good* people: more likely to treat others well, and better able to succeed in important human endeavors. Over the past decade, environmental virtue ethicists have worked to specify those character traits that we will have to exemplify as citizens of truly sustainable societies (Sandler, 2007). They include:

- justice, in our treatment of other species and one another;
- generosity, involving a willingness to go beyond the demands of justice in sharing resources;
- temperance, shown in an ability to limit our cravings for more wealth and possessions and to act with self-control;
- prudence, in order to think long-term and follow the dictates of reason regarding grave environmental threats;
- attentiveness, to the beauty and complexity of nature;
- gratitude, in appreciating what we have and taking the time to give thanks for it, rather than always hankering after more;
- wisdom, in recognizing the real value of this world we live in, knowing how to live well within it, and acting on that knowledge (Cafaro and Sandler, 2010).

The claim, a new one in the history of philosophy, is that just as no one can be a virtuous person if they do not treat

Table 1 The dominant anthropocentric philosophy contrasted with deep ecology

<i>Dominant worldview</i>	<i>Deep ecology</i>
Humans dominant over nature	Humans living in harmony with nature
Natural environment and species are resources for humans	All nature has intrinsic worth, regardless of human needs
A growing human population with a rising standard of living	A stable human population living a materially simple life
Earth's resources are unlimited	Earth's resources are limited and must be used carefully
Ever higher technology brings progress and solutions	Appropriate technology must be used with respect for the Earth
Emphasis on material progress	Emphasis on spiritual and ethical progress
Strong central government	Local control, organized according to watersheds, bioregions, or other natural units

other people justly, so no one can be a virtuous person if they do not live sustainably themselves and further efforts to create sustainable societies. It would be nice if we could just rearrange our institutions a bit, perhaps build in a few more safeguards, and preserve biodiversity and the essential ecosystem services that we depend on, without having to change ourselves. But that seems unlikely. From here onwards, in the busy, crowded world we have created, human excellence, well-being and sustainability are necessarily intertwined.

Some readers may see such talk as utopian, or even a counsel of despair. If it is hard to imagine radical economic change, it is even harder to imagine radical changes in human nature. Furthermore, in a democratic age, we are not used to demanding that our fellow citizens become better people. However, these changes do not have to happen all at once, or solely as a matter of individual willpower. Instead, we need to begin reforming our institutions, so that they help create better people over time: Schools that educate new citizens who are just, temperate, and generous, in addition to knowledgeable about nature and environmental issues; economies that create intelligent consumers whose purchasing decisions are thoughtful and restrained, rather than intemperate. Who is to say that such changes are impossible? The career of *Homo sapiens* may be just beginning! Perhaps human beings can be much more than we are now. Perhaps we will have to be, in order to preserve biodiversity.

Humanism: Our Default Philosophy

Like deep ecologists, many conventional ethical philosophers, have begun to address environmental issues. Most philosophers who have considered these matters (including deontologists, utilitarians, social contract theorists and theologically-grounded ethicists) have found strong reasons to support environmental protection (Schmidtz and Willott, 2012). As previously noted, biocentrists and anthropocentrists may agree on a wide range of practical measures to protect the environment, despite large philosophical differences.

Still, some philosophers and many members of the general public remain unconvinced of any moral imperative to protect biological diversity. Their position may be characterized as humanism, a philosophy committed to the following propositions (Ferry, 1995; Lomborg, 2010):

1. Biological diversity exists for humans, has no value apart from humans, and need not exist apart from humans.
2. The continued transformation of wild nature into natural resources adds value to nature, since nature possesses value only in human use. Indeed, the ever more thorough transformation of wild nature allows greater numbers of people to lead longer, happier, and better lives.
3. The creation of just societies filled with flourishing individuals is the highest achievement of which humans are capable. We should judge ourselves based on our technological, scientific, artistic, and social progress – not on whether we preserve nature.

Like other environmental philosophies, humanism may be developed in a variety of ways. A humanist's ideal society may be more or less egalitarian, more or less wealthy, more or less

racially and culturally diverse. But humanists share a belief in the centrality of humans. They generally applaud increased human numbers, wealth, and technological power, and the development of new arts and activities that flourish in highly artificial environments. For these reasons they see little to lament in the loss of biodiversity.

A main motivation for embracing humanism is its rejection of limits to growth. Limiting both population growth (Grant, 2006) and economic growth (Czech, 2002) is essential to preserving biodiversity. But even many proponents of biodiversity protection shrink from defending explicit limits to growth. Two spectacular recent examples of this failure were the 2005 Millennium Ecosystem Assessment (MEA) and the 2007 4th Assessment Report of the Intergovernmental Panel on Climate Change. In laying out future scenarios for detailed consideration, the authors of the MEA, who included numerous biologists and ecologists, failed to include any which explicitly limited economic growth. This meant that all the scenarios they considered included massive biodiversity loss. The IPCC's 4th Assessment Report identified the primary causes of climate change as unremitting economic and demographic growth, and warned that under "business as usual," the world courted potentially disastrous levels of global warming. Yet their detailed discussion of measures to limit (or "mitigate") climate change, which ran to many hundreds of pages, failed to consider measures which would directly limit such growth. Instead, they focused nearly exclusively on technological improvements to accommodate more growth – an obviously self-defeating approach.

When even nature's defenders refuse to question the necessity and goodness of continued growth, we see the powerful hold this ideal has on the contemporary mind (Moore and Nelson, 2010). This refusal to probe growth appears to motivate many climate change deniers, for how could something so good result in such disastrously bad consequences? It lies behind the willingness to consider radical geoengineering schemes, such as seeding the oceans with iron or pumping aerosols into the stratosphere – rather than embracing simpler, cheaper, and more obvious solutions to climate change which involve economic and demographic restraint. Of course, as with biodiversity preservation, there are ample human-focused reasons for opposing climate geoengineering, based on its uncertain impacts on future generations of people. But we should also be impressed by its breathtaking anthropocentrism, which typically goes unremarked in the scientific literature and popular press. In effect, such proposals accept that Earth, which over eons has been home to an amazing and ever-increasing diversity of hundreds of millions of species, will henceforth be managed for the benefit of a single species. Us.

In the end, more people and more human economic activity equal less biodiversity: more of us equals less of them. So as a practical matter, whether or not our responses to climate change, species extinction, ocean acidification, and other global environmental challenges accept or reject limits to growth, will answer the question of whether we are biocentrists or anthropocentrists, deep ecologists or confident planetary managers. As Aldo Leopold (1987) noted, we write our environmental philosophies on the land itself (and in the air and under the seas). Our answers will be clear, in the

presences and absences, the sounds and silences which remain after we are gone.

Humanism may be called humanity's default mode, since current trends are moving us more and more in this direction, whether it is desirable or not. We are creating a world with much less biological diversity and this artificial world has come to seem normal, indeed natural, to many people. It is not, however, inevitable. Human beings can reconnect to nature and curb the activities which threaten it. Environmental ethics reminds us that we have many reasons to value and protect Earth's remaining biological diversity. The next hundred years should tell us a lot about whether self-proclaimed *Homo sapiens* really is wise, or merely clever.

Glossary

Algae (sing., alga; adj., algal) Primitive plant-like organisms that generally photosynthesize, here including cyanobacteria (sometimes called blue-green algae). These organisms can be unicellular, filamentous, or colonial microscopic forms (microalgae), or they can be macroscopic (macroalgae) consisting of a primitive plant body (thallus) that lacks vascular tissue in most species.

Anoxia (adj., anoxic) Condition in which there is negligible or no dissolved oxygen (DO) in the water (<0.1 mg of DO l^{-1}).

Biochemical oxygen demand (BOD) Measure of the DO required by the microbial community to decompose organic matter by aerobic metabolism.

Harmful algae Algae that are undesirable to humans because they: (1) become too abundant, or “bloom,” in response to nutrient over-enrichment and then, at night, use most or all of the oxygen in the water for their respiration, so that the fish and other desirable organisms suffocate or become seriously physiologically stressed; (2) become too abundant in response to nutrient enrichment, and overgrow beds of desirable rooted vegetation so that the beneficial plants cannot receive enough light to survive; (3) cause or promote disease in desirable plants or animals; and/or (4) produce toxins that hurt or kill finfish, shellfish, and other higher trophic levels including humans. More recently, the term has been used to also include organisms that are not photosynthetic, primitive plantlike organisms – for example, certain nontoxic animal-like dinoflagellates, which cause fish disease (e.g., *Amyloodinium ocellatum*); and certain toxic animal-like dinoflagellates (e.g., toxic *Pfiesteria piscicida* and *Pfiesteria shumwayae* described by Burkholder and colleagues (2005), Marshall and colleagues (2006), and Moeller and colleagues (2007)), which do not have their own chloroplasts for photosynthesis, but which resemble plantlike toxic dinoflagellates in appearance and certain other general features. The term also commonly includes cyanobacterial (blue-green-algal) blooms (proliferations), despite the fact that in taxonomy they are now formally classified as bacteria rather than algae. They are included because cyanobacteria are primary producers and, so, function ecologically as photosynthetic algae.

Hypoxia (adj., hypoxic) Condition in which the water has depressed DO levels that generally are too low to sustain healthy populations of most fish species for extended periods (usually considered as >0.1 to <2 mg DO l^{-1} ; sometimes <4 or <4.5 mg DO l^{-1}). Note that hypoxic levels of 3–4 mg DO l^{-1} can stress or kill sensitive egg and larval stages of some finfish and shellfish species, and that many fish actively avoid hypoxic areas.

Mixotrophy (adj., mixotrophic) Form of nutrition involving both phototrophic (photosynthetic) and heterotrophic carbon acquisition.

Nutrient (ecological or elemental) stoichiometry The study of changes in the relative proportions of critical nutrients available in the water, relative to differences in the allocation of these elements in organisms (*sensu* Sterner and colleagues). It may also refer to the relative availability of critical elements in ecosystems, as both an influence on and an overall result of interactions among biota and system biogeochemistry. Nutrient or ecological stoichiometry dictates that the relative availability of critical elements determines which of those elements most constrains the ecological dynamics (*sensu* McIntyre and Flecker). More specifically, nutrient stoichiometry compares nutrient ratios (especially N, P, carbon, and silica) in solution versus biomass.

Salt wedge Water from the ocean, with higher salt content, that moves into an estuary along the bottom of the water column, beneath less dense freshwater that has moved into the same area from a river. The salt content makes the ocean water heavier than the fresh (riverine) water, so that under calm conditions, the estuarine water becomes density-stratified. This “salt wedge” of bottom water can become somewhat isolated from the overlying fresh or less brackish water. The longer the period in which the total water column is not mixed by winds or storms, the more distinct the two water layers or strata. Salt wedges most often develop in warm seasons when plantlike phytoplankton production is high in the surface waters and respiration by heterotrophs (bacteria, fungi, protozoans, animals) is also high, especially in the lower water column and sediments. Nutrients typically are higher within the salt wedge than in the overlying water because of decomposition processes. At the same time, the bottom-water salt wedge can become hypoxic or even anoxic, while overlying waters can be saturated or supersaturated with oxygen from phytoplankton photosynthesis.

Stoichiometric imbalance A unique, forced trophic state in an aquatic ecosystem that develops when one nutrient, generally nitrogen (N) or phosphorus (P), but not both, is altered, either due to enrichment or management-related nutrient control. Stoichiometric imbalance can occur throughout the eutrophication process, depending on the enrichment sources or timing of N or P controls.

Trophic status Ranking system for aquatic ecosystems, based on the amount of organic production and nutrient (N, P) levels. Qualitatively, consists of three categories: Oligotrophic – characterized by relatively high phytoplankton species diversity but low phytoplankton

production, low nutrient concentrations and loadings, low decomposition (with little organic material available to decompose), and plentiful DO throughout the water column. Mesotrophic – characterized by moderate phytoplankton production and moderate nutrient concentrations and loadings. Eutrophic – characterized by relatively low phytoplankton species diversity but high phytoplankton production (often dominated by cyanobacteria in lakes, and by dinoflagellates or other flagellates in estuaries), high nutrient concentrations and loadings (especially of nitrogen (N) and phosphorus (P)), high decomposition in the bottom water and surficial sediments (with abundant organic materials available for this process), and bottom-water DO deficits, sometimes

with occasional to frequent fish kills. Eutrophic lakes typically are shallow with well-developed littoral zones (area where light penetration is sufficient to support growth of rooted plants), sometimes extending across most or all of the bottom area. Based on these classic definitions, the major component that is usually considered in assigning trophic status is phytoplankton, but this approach can be misleading. For example, some lakes are classified as oligotrophic because water-column nutrients and phytoplankton production are low, despite the fact that benthic primary production (e.g., of rooted angiosperms and their algal epiphytes) may be high. Quantitative rankings have also been developed, such as the Trophic State Index developed for lakes by Carlson (1977).

Introduction

Historic Overview Across Aquatic Habitats and Present Realities

From freshwater lakes to estuaries and marine coasts, human-derived sources of nutrient pollution have rapidly changed water quality and aquatic community structure within the past *ca.* 230 years of industrialization and rapid population growth (Cloern 2001, Wetzel 2001, Boesch 2002). The predominant theme throughout most of the world is increased nutrient enrichment or cultural eutrophication, rather than nutrient decreases or oligotrophication; thus, eutrophication is emphasized here although both processes are addressed.

Despite the advances in treatment of human sewage in some countries during the late twentieth century, bans on use of phosphorus in certain domestic or industrial practices, declines in agricultural fertilizers in some geographic regions, and modest improvements in environmental education in localized areas, the massive recent and ongoing increase in global human population growth has increased nutrient loadings to aquatic ecosystems (Figure 1). These increases are greatest in estuarine and coastal marine areas where

population growth has been highest, and where nearly two-thirds of the people of the world now reside. As a reflection of this trend, estuaries have been reported to receive more nutrient inputs per unit surface area than any other type of aquatic ecosystem (Figure 2).

Cultural eutrophication promotes major shifts in the structure of both plant and animal communities, generally affecting dominant components of every trophic level from microbial decomposers to macrofauna. There is clear, compelling evidence of altered aquatic community structure and significantly reduced biodiversity from nutrient over-enrichment in many freshwater, estuarine, and marine ecosystems. Surface waters across the earth are now sustaining such impacts; even the open oceans are no longer sufficiently isolated to avoid nutrient pollution from atmospheric deposition. Similar trends have been demonstrated from the microfossil records of lakes and estuaries, showing a dramatic increase in nutrients and associated organic carbon deposits and a sharp, sustained decrease in the diversity of aquatic species.

Nutrients are essential for primary production by phytoplankton, benthic micro- and macroalgae, and aquatic

Figure 1 (a) The relationship between population density in watersheds and export of soluble reactive phosphorus (SRP) in river water, considering 32 major rivers (Caraco, 1995). (b) Export of total nitrogen from watersheds surrounding the North Atlantic Ocean, as a function of net anthropogenic inputs to their watersheds. Net anthropogenic inputs are defined as industrial N fertilizer + N fixation by legume crops + atmospheric inputs of oxidized N + net imports of N in food and feedstock. From Howarth *et al.* (1996), *Biogeochemistry* 35, 181–226 Figure 5A, with permission from Kluwer Academic Publishers.

angiosperms that directly or indirectly support aquatic food webs. In freshwaters, phosphorus historically has been least abundant among the nutrients needed in large quantity (macronutrients) by primary producers (Hecky and Kilham, 1988; Wetzel, 2001). Thus, it often has been the first element to become limiting to primary productivity in many freshwater systems, with nitrogen being secondary in importance

Figure 2 Phosphorus and nitrogen inputs to various types of ecosystems, showing the highest nutrient enrichment for estuaries and coastal waters. Reprinted with permission from Wassmann (2005) *Eutrophication, primary production and vertical export*, Figure 9.1. In: Wassmann P and Olli K (eds.) *Drainage Basin Inputs and Eutrophication: An Integrated Approach*, pp. 126–138. Norway: University of Tromsø. Available at: <http://lepo.it.da.ut.ee/~olli/eutr/Eutrophication.pdf>

(Figure 3). Total phosphorus (TP) is typically considered in evaluating freshwaters for P limitation, rather than inorganic P (Pi – phosphate, PO_4^{-3}) which is the form most often used by algae. TP is used because algae commonly take up and store more P than they need in a process called luxury consumption. In natural systems or surface waters that are affected only by low anthropogenic inputs, PO_4^{-3} ions are rapidly taken up by algae and bacteria as fast as they are released, sometimes within seconds, so PO_4^{-3} concentrations typically appear to be low ($<5 \mu\text{g l}^{-1}$) yet offer only a “glimpse” of the P actually available for algal growth. However, in areas that are strongly influenced by anthropogenic nutrient enrichment – such as sewage discharges from treatment plants with only primary or secondary treatment, or discharges from large phosphate mines – PO_4^{-3} concentrations can be $0.5\text{--}2 \text{ mg l}^{-1}$ or more. Phosphorus also has been the most important nutrient-limiting plant growth in many tropical coastal marine waters and certain pelagic ocean waters (Downing, 1997; Burkholder *et al.*, 2007, and references therein). In temperate and polar coastal marine environments, nitrogen historically has been the most important nutrient that first limits primary production. Inorganic N (Ni), especially nitrate (NO_3^-) and ammonia (NH_3) and its ionized form, ammonium (NH_4^+), is directly taken up by phototrophs, although certain organic N forms such as urea can also be important N sources (Hecky and Kilham, 1988; Smith, 2006). Similarly as for Pi, in some cases Ni concentrations may appear to be low in the water column, but the total availability can be much higher due to rapid regeneration and biological recycling. At the estuarine interface between marine and freshwater habitats, both N and P can colimit plant production, especially in late winter-spring seasons of high precipitation and accompanying high inorganic N inputs. Other nutrients, notably silica and iron,

Figure 3 Relationship between summer maximum chlorophyll *a* content and (a) TP or (b) TN in surface and near-surface waters of some lakes in Japan. Numbers next to points represent the N : P ratio (by mass). Note that lakes with exceptionally low and exceptionally high N : P ratios are outliers in the TP-chlorophyll *a* and TN-chlorophyll *a* relationships, respectively. Similar log-log relationships between TP and chlorophyll *a*, and between TN and chlorophyll *a*, are characteristic of many natural lakes in the world that have low abiotic turbidity. Modified by Sakamoto (1966) in Kalff J (2002) *Limnology*, Prentice Hall, Upper Saddle River, NJ, with permission from Jacob Kalff and Pearson Education.

Figure 4 The pervasive influences of changes in ecological (nutrient) stoichiometry, showing expected changes in various components of a generalized aquatic food web as the water-column N : P ratio increases, based on ecological stoichiometry principles. The upper panel depicts the trend in water-column N : P ratios over time. Modified from Glibert *et al.* (2011) Long-term changes in nutrient loading and stoichiometry and their relationships with changes in the food web and dominant pelagic fish species in the San Francisco Estuary, California. *Reviews in Fisheries Science* 18: 358–417.

can sometimes significantly influence the outcome of species dominance and the structure and abundance of phytoplankton assemblages under cultural eutrophication.

Although scientists still evaluate surface waters in terms of N or P limitation in this way, it is important to note that these key nutrients are, in fact, no longer limiting in many freshwaters, estuaries, and coastal marine ecosystems. Instead, as Glibert *et al.* (2011) have pointed out, it is the *excess* of N and P loads that is at issue in present-day waters, not the lack of supply. The apparent strength of N limitation in marine waters, or of P limitation in freshwaters, is overestimated under conditions of P and N enrichment, respectively. Moreover, from an analysis across terrestrial and aquatic ecosystems, Elser *et al.* (2007) found that there tend to be strong

positive synergistic effects of combined N and P enrichment; and that, because N and P supplies are closely balanced, single enrichments (of N but not P, or of P but not N) tend to rapidly promote limitation by the alternative nutrient. Nutrient or ecological stoichiometry relates changes in the relative composition of N and P in cells and tissues of aquatic organisms versus the water column. At the level of community dynamics and structure, changes in nutrient ratios, especially the relative proportion of N and P, alter metabolism, species composition, and food webs (Figure 4). Systems that are manipulated stoichiometrically by adding or reducing N or P, but not both nutrients, are neither eutrophic or oligotrophic. Application of traditional eutrophication indices will lead to an erroneous conclusion that such systems are not nutrient-stressed when,

in reality, they have been forced out of balance. They are in a state of stoichiometric imbalance.

In moderation, nutrients promote beneficial increases in phytoplankton and benthic algal production and, in turn, higher production of zooplankton, macroinvertebrates, shellfish, and finfish. But when added in excess, nutrient pollution can cause overgrowth of micro- and macroalgae, leading to dissolved oxygen (DO) depletion in bottom waters and sometimes even throughout the water column, and also causing alterations in food web dynamics. The classic symptoms of eutrophication are an increase in suspended algal chlorophyll (indicator of algal biomass), high-biomass algal blooms, a decline in submersed aquatic vegetation (SAV), and increased DO deficits and increased variation in DO over a diel (24-h) period. Schindler (1987) noted that among the earliest responses to anthropogenic stressors such as nutrient pollution is the loss of sensitive species. Although fish kills can be an obvious sign of acute impacts from cultural eutrophication, associated more subtle, chronic impacts are much more damaging to aquatic communities over the long term because they cause large-scale alterations in habitat and major shifts in aquatic food webs. Sustained loss in biodiversity is foremost among these chronic impacts, resulting from underlying mechanisms that scientists are only beginning to understand.

Factors Influencing Impacts from Nutrient Enrichment

Among the most important factors that influence the extent of adverse impacts from nutrient enrichment is water exchange rate, or the time required to completely replace the water in the system with new water. Waters that can self-cleanse or rapidly flush, such as fast-flowing rivers or run-of-river impoundments, are less sensitive to elevated nutrient loading than more contained or enclosed waters such as lakes and estuarine lagoons. Similarly, waters along open, wave-swept marine coasts are less sensitive to nutrient loading than quiet, sheltered upper embayments. However, such flushing may only displace the nutrient impacts by moving them downstream or to another area. Thus, countering the old adage that 'the solution to pollution is dilution', dilution is not the solution to eutrophication. The occurrence of other pollutants along with nutrients – for example, suspended solids that can reduce light for growth of aquatic plants, or toxic substances and harmful bacteria that can stress or kill some aquatic species – can exacerbate impacts from nutrient enrichment. The nutrient form can also be important. For example, swine wastes are much richer in organic nutrients (N, P, and C) than untreated human sewage. Various harmful algae prefer organic nutrient forms over inorganic sources.

The timing and frequency of the source inputs are important, as well. During high-precipitation periods in winter, sewage is more effectively diluted and cold temperatures discourage the growth of many nuisance algae. Also, in some waterways, agriculture is the major source of nutrients annually, but during low-flow periods in warmer seasons, sewage can contribute half or more of the river volume and the loading of nutrients – at a time when the readily available nutrients stimulate noxious algal overgrowth of the system.

The initial aquatic community structure also influences the overall effects of nutrient loads to aquatic ecosystems. Systems with low nutrient enrichment rely more on recycled nutrients than on introduction of new nutrient sources, and this may be a driving evolutionary force leading to greater specialization and diversity, as suggested by Howarth (1988). Diverse communities, characteristic of oligotrophic or nutrient-depauperate waters, tend to be dominated by sensitive species that thrive only within a narrow range of environmental conditions. Oligotrophic ecosystems are more sensitive (or less resistant), overall, to stress from nutrient enrichment. The most predictable outcomes are loss of sensitive species and increased abundance of generalist or opportunistic species that apparently are more resistant to the undesirable water quality changes and other stresses resulting from nutrient pollution. As an ecosystem becomes more eutrophic (that is, increasingly stressed by eutrophication), it becomes more resistant to further change.

Increasingly eutrophic lakes, lower rivers, and estuaries are characterized by seasonal low oxygen stress in the bottom waters, sometimes extending throughout half or more of the water column. Low oxygen stress can also occur within dense algal blooms near the water surface. Acute hypoxia or anoxia can result from allochthonous or external inputs of organic wastes, such as sewage discharges or runoff from animal feedlots, whereas chronic low-oxygen conditions can result from within-system (autochthonous) processes such as respiration by dense algal blooms or decomposition of dead remains of those blooms. Total organic carbon (TOC) is often used as a sum parameter for eutrophication (Figure 5); high organic content usually translates into an increase in the growth of microorganisms that will decompose the wastes using aerobic respiration, often causing oxygen depletion in the system as more and more TOC is produced because of nutrient over-enrichment. In general, the higher the rate of biological metabolism (photosynthesis, respiration), the higher the TOC. Organic contaminants from agricultural runoff and domestic and industrial wastes also add TOC that contributes to the oxygen demand required by decomposers.

Hypoxia and anoxia develop when oxygen consumption exceeds supply, as a result of two major factors. In ecosystems with sufficient light to support their growth, the algae – often in densities of millions to billions of cells ml^{-1} of water – typically are the first to be stimulated by nutrient enrichment. They are net producers of oxygen through photosynthesis during the day, but at night they consume oxygen for respiration. Dense populations of algae in the upper and mid-depths of the water column can consume most of the DO. Low-oxygen stress in the system also occurs because of increased decomposition. As algal blooms senesce and die, and plants and animals die and settle out over the growing season, their remains are decomposed by bacteria and fungi in oxygen-demanding processes that can rapidly deplete the oxygen from the lower water column, sometimes extending to mid-depths or shallower. Oxygen solubility decreases with increasing temperature. Thus, low-oxygen stress tends to be most pronounced in warmer seasons when algal biomass, decomposition rates, and respiratory rates (and oxygen requirements) of fish and other animals are generally high.

Figure 5 (a) Relationship between TP and TOC in some US reservoirs ($n=34$) and natural lakes ($n=3$). (b) Relationship between suspended algal biomass (as chlorophyll *a*) and TOC in some US reservoirs ($n=18$) and natural lakes ($n=2$). Modified from Figures 2 and 3 in Walker Jr. WW (1983) Significance of eutrophication in water supply reservoirs. *Journal of the American Water Works Association* 75: 38–42.

Low-oxygen conditions are exacerbated when bottom waters become somewhat isolated from the upper water column that receives oxygen during the day from phytoplankton growth, as well as throughout the diel cycle from the overlying air as it diffuses into the water. The isolating effect occurs when the water column becomes thermally (density) stratified, as in the bottom water layer (hypolimnion) of a stratified lake; or salinity (density) stratified, as in the lower water-column salt wedge in an estuary. As a result, sessile bottom-dwelling animals become physiologically stressed and may suffocate unless they can slow their metabolism until oxygen is replenished. Motile animals that rely on the bottom waters as critical nursery areas for their young, or a refuge area to escape predation, can physically avoid the low-oxygen areas but may nevertheless suffer population declines because of critical habitat loss. NH_3 that is released from decomposed organic matter, and its ionized form NH_4^+ , can accumulate to toxic levels (see Aquatic Fauna and Inorganic Nitrogen Toxicity, below) in anoxic waters at depth, which further contributes to habitat degradation.

Organic matter in poorly treated sewage and animal waste contributes to low-oxygen stress in aquatic systems, as another source of material for decomposition or biological oxygen demand (BOD) (National Research Council, 1993; Mallin *et al.*, 2006). Chemical oxygen demand may further deplete oxygen, through oxidation of high levels of ammonia and other inorganic reduced compounds in the wastes. These oxygen-demanding processes often are relatively localized problems, for example, near sewage outfalls or animal waste spills, although they can affect the lower water column of eutrophic systems for months or even as a chronic condition. In addition, certain oxidized nutrients such as NO_3^- are highly soluble in water and, therefore, can be transported considerable distances as shown, for example, work by Mallin *et al.* (1993, 2005) or studies of NO_3^- from agricultural lands of the upper midwestern US contributing to an expansive low-oxygen “dead zone” in the Gulf of Mexico by Turner *et al.* (1998). Thus, transport creates a time lag between the introduction of nutrients into one area and adverse impacts at some distance from the source. Oxygen consumption from

decomposition of excess phytoplankton production thus can occur on a large scale that is difficult to track or to relate to one specific, original source.

Changes in Flora and Fauna

Microalgae

Species Shifts Across Nutrient Gradients

Phytoplankton dominate the flora of oligotrophic systems. They respond quickly to nutrient inputs because the tiny plantlike organisms are immersed in the enriched medium, in contact with it over all surfaces. Phytoplankton with optimal growth at elevated nutrient concentrations are especially stimulated or selected for by nutrient enrichment, and they eventually overgrow and replace species that grow best at lower nutrient levels (Hecky and Kilham, 1988). Along a gradient from oligotrophic to highly nutrient-enriched, the phytoplankton assemblage structure gradually shifts from low abundance of many species and dominance by small flagellates and picoplankton (algae $<2\ \mu\text{m}$ in diameter) – with much of the energy flow channeled through a microbial loop of bacteria and small flagellates rather than directly up the food chain to herbivorous zooplankton – to high abundance of relatively few species consisting mainly of large cells or large colonies along with seasonally abundant flagellates. As lakes, lower rivers, and estuaries become more eutrophic, diatom (Heterokontophyta) species with higher N and P optima predominate in colder periods, certain colonial green algae (Chlorophyta) with high N optima become abundant in early summer, and dinoflagellates (Dinophyta: *Gymnodinium* spp., *Peridinium* spp.) and filamentous and colonial cyanobacteria with high P optima dominate in late summer. If dissolved silica, needed by diatoms to make their cell walls, is limiting in colder seasons, then flagellates (as examples, dinoflagellates, cryptomonads, euglenoids) become more abundant.

In shallow freshwater lakes, estuaries, and lagoons where open water habitat is limited, high phytoplankton densities can occur in response to nutrient enrichment (e.g., high

flagellate densities that historically occurred in response to excrement from duck farms in western Long Island Sound (Rhyther, 1989)). More commonly, benthic algae known as epiphytes (growing on the leaves of SAV), or floating drift macroalgae (in sheltered estuarine and marine coastal embayments), are rapidly stimulated by the nutrient increases and restrict the light needed by underlying plants (Figures 6 and 7). Increased nutrient enrichment generally promotes a decrease in species diversity of benthic algae, and a shift in dominance from diatoms to filamentous green algae or cyanobacteria. The planktonic and (more so) benthic habitats in such systems are characterized by a combination of low light and abundant food resources in the form of smaller organisms and rich dissolved organic substrates. These conditions also select for mixotrophic microalgae, including an array of harmful taxa that can become abundant and diverse under eutrophic conditions (Burkholder *et al.*, 2008; Jeong *et al.*, 2010).

Many regions of the world have landscapes dominated by run-of-river impoundment or reservoirs, rather than natural

lakes. Similar trends in impacts from nutrient loading on aquatic communities can occur over time in reservoirs as in lakes, with the exception of depauperate rooted macrophyte populations (*see* Macrophytes, Aquatic Vascular Plants, below) in reservoirs with variable depth imposed by controlled drawdowns in potable water supply management or flood control. Impacts of cultural eutrophication in reservoirs can be mitigated by rapid water exchange, which generally occurs in weeks to months, rather than in years as for most natural lakes (Wetzel, 2001, and references therein). Moreover, the high turbidity from sediment loading or resuspension, characteristic of many reservoirs and estuaries as well as some natural lakes, often makes available light – rather than nutrients – the primary resource limiting the productivity of phytoplankton and other flora in the systems. Nutrients act as secondary factors controlling plant growth under such conditions, although they can become primary limiting factors if the water clears (for example, between storm events). Such systems often

Figure 6 Generalized relationship of primary productivity of major plant groups in lakes under increasing nutrient enrichment. Nutrients are the primary resources limiting plant production under oligotrophic conditions, and phytoplankton (low in abundance and relative primary productivity, but high in species diversity) predominate over other phototrophs. As eutrophication progresses with increasing nutrient enrichment, light becomes more important than nutrients as the primary resource limiting primary production. In mesotrophic conditions prior to the onset of light limitation, submersed macrophytes can dominate, but they eventually are eliminated because of low light availability and emergent plants predominate. In late stages of the aging process, lakes become increasingly shallow and gradually function as wetlands. Plant production is then limited primarily by the availability of water. Reprinted with permission from Wetzel RG (2001) *Limnology*, 3rd edn., New York: Academic Press; originally from Wetzel RG (1979) *The role of the littoral zone and detritus in lake metabolism*. *Archives für Hydrobiologie Beiheft Ergebnisse der Limnologie* 13: 145–161.

Figure 7 Generalized shift in biomass of major groups of primary producers with increasing nutrient enrichment to shallow and deeper coastal marine waters (upper and lower panels, respectively). In this generalized format, nutrients limit primary production under oligotrophic conditions. As eutrophication progresses with increasing nutrient enrichment, light becomes the primary limiting factor. Macroalgae (in shallow waters) or phytoplankton (in deeper waters) dramatically increase and become dominant, while seagrasses decline. Direct underlying mechanisms include competition for light and nutrients and also, for some species, NO_3^- inhibition or NH_4^+ toxicity. Reproduced from Burkholder *et al.* (2007) *Journal of Experimental Marine Biology and Ecology* 350: 46–72, Elsevier. (Note: The upper panel was Figure 3 in the previous version of this chapter. It was originally from Harlin (1993) *Changes in major plant groups following nutrient enrichment*. In: McComb (ed.) *Eutrophic Shallow Estuaries and Lagoons*, pp. 173–187. Boca Raton, CRC Press, Inc.)

can sustain higher nutrient (especially P) loading than clear, natural lakes while supporting less phytoplankton biomass, because of more rapid water exchange and light limitation from high suspended sediments. However, it must be underscored that in such cases, the nutrients that are not retained in the system (e.g., by settling out to the bottom sediments) will be transported downstream, where they can support increased production and lead to eutrophication impacts (e.g., Houser and Richardson, 2010; Jacobson *et al.*, 2011).

“Bottom-up” control by nutrients interact with grazing pressure from zooplankton and other fauna in “top-down” trophic level effects (Carpenter, 1988; Burkholder *et al.*, 2007, and references therein). Such effects are well documented in freshwater lakes and streams, and can also be operative in estuaries and coastal marine waters. Many field and laboratory studies have demonstrated that proliferation of phytoplankton and benthic microalgae under nutrient enrichment (e.g., seagrass epiphytes as described by Neckles *et al.*, 1993) can be significantly reduced during periods when grazers are abundant. Thus, herbivores can sometimes alleviate eutrophication impacts by holding algal production in check. However, one effect of grazing pressure is to transform the form of nitrogen available to primary producers. Animals excrete nitrogen in the form of NH_4^+ (or, in some cases, urea), that is used by primary producers at a different rate than is NO_3^- . Different algal species can be stimulated by NH_4^+ than by NO_3^- .

Decreased grazing pressure can allow higher algal biomass to develop in response to excess nutrients, but decreased grazing can help promote algal blooms only where nutrient inputs are sufficiently high to support such blooms. Therefore, grazing pressure – especially in present-day aquatic ecosystems – is generally regarded as a secondary factor controlling phytoplankton production under cultural eutrophication. Moreover, human hunting practices have caused severe reductions in what likely were once major influences of large herbivores in aquatic food webs, such as waterfowl across the salinity gradient, and green turtles (*Chelonia mydas*, sirenians) in marine food webs. Thus, in considering many present-day temperate regions in particular, Valentine and Duffy (2006) described large grazers mostly as “ghosts” because their once-major influence in many seagrass ecosystems has been reduced to such an extent that it is now “extremely episodic, negligible, or absent.”

Long-Term Human Influences of Cultural Eutrophication

Long-term datasets have provided two lines of compelling evidence in support of major impacts from cultural eutrophication on phytoplankton assemblage structure in aquatic ecosystems, with potentially serious ecological and economic ramifications. First, the geological record in sediment cores taken from freshwater lakes and estuaries clearly shows that long-term major shifts have occurred under increased nutrient enrichment – progressing from a balance between species-rich planktonic (mostly centric) and benthic (mostly pennate) diatom assemblages, to dominance by planktonic diatoms with low species diversity (Figure 8). Planktonic diatoms tend to be selected because they are the first recipients of the increasing water-column nutrient sources. Benthic diatoms encounter decreased light because of the

overlying plankton growth, eventually leading to decreased production.

The second line of evidence concerns species shifts in extant phytoplankton assemblages that have been related to changes in supply ratios of the two most limiting nutrients, again underscoring the importance of ecological stoichiometric considerations. Under nutrient-limiting conditions, species with similar optima in other environmental factors (e.g., temperature or light) that maintain faster growth compete more successfully for the available nutrient resource (Figures 9–11). Elegant work by Tilman (1977) and Tilman *et al.* (1982) examined the response of freshwater diatom species to shifts in Si : P ratios, and Rhee (1982) extended these concepts to controlling influences of N : P ratios. Low molecular N : P ratios (7–15 in those studies; up to ca. 29 : 1 by weight in Smith (1983)) favored tested cyanobacteria and diatom species, whereas higher N : P ratios favored green algae. Many green algae grow optimally at high N_i concentrations, whereas many cyanobacteria and dinoflagellates have a high P requirement. Diatoms, unlike the other algae, require major supplies of silica as well as N and P. When Si : N and Si : P ratios are high, the available Si favors growth of diatoms that can effectively compete for N and P resources. However, as Si : N and Si : P ratios decrease, silica can become limiting for diatom growth, and more N and P remain available for growth of flagellates and other algae that do not require silica. These concepts were extended to natural lakes by Tilman *et al.* (1982) (for diatoms and other algae), Smith (1983) (for cyanobacteria), and others.

Silica is only slowly (years) made available for new diatom growth through dissolution of dead diatoms and other natural silica sources, although it can also be affected by installing dams that can trap sediments and reduce silica availability. In contrast, N and P cycles are rapidly affected by anthropogenic inputs from sewage, animal wastes, atmospheric pollution, and other sources. As N and P enrichment increases, the Si : N and Si : P supply ratios are depressed. Eutrophication can effect a decrease in dissolved Si abundance by initially stimulating high growth of diatoms to the point that they reduce or deplete the dissolved silica pool for use by developing diatom populations in subsequent seasons. Long-term datasets on estuarine, coastal, and freshwater phytoplankton communities indicate that shifts to dominance by flagellated algae or cyanobacteria – including some harmful bloom-forming species – have coincided with decreased abundance of diatoms and decreased Si : N and Si : P ratios. Such trends have been documented by Schelske *et al.* (1986), Smayda (1989), Parsons *et al.* (2002), and others in temperate and sub-Arctic waters such as the Great Lakes, New England coastal waters, Chesapeake Bay estuarine waters, the Black Sea, and the coasts of northern Europe. In the Gulf of Mexico near the mouth of the Mississippi River, increasing N (nitrate)- to- Si ratios have been related to an increase in weakly silicified diatoms, including potentially toxic *Pseudo-nitzschia* species, which like other diatoms, are stimulated by nitrate pollution but they also require less silica for their cell walls relative to many other diatoms. In oligotrophic subtropical and tropical marine waters, mixotrophic dinoflagellates can predominate and, symbiotic interactions are common in both planktonic and benthic communities. As these systems undergo cultural

Figure 8 The geological record of cultural eutrophication in Chesapeake Bay, showing major changes since European settlement. The data from four sediment cores are graphed by the average date assigned to each sediment sample (depth layer) according to radiocarbon and pollen methods. (a) Total organic carbon (TOC, indicating total system productivity) preserved over time (historic record from AD 150 to AD 1990). (b) Diatom cell numbers per year (AD 400–AD 1990). (c) Diatom assemblage diversity calculated as Shannon's H' (AD 400–AD 1990). (d) Centric/pennate diatom ratios (AD 400–AD 1990). TOC, diatom numbers, and the centric/pennate diatom ratios all showed a significant and abrupt increase following the time of European settlement in the 1700s. The total diatom community diversity, in contrast, significantly decreased post-1700s, relative to pre-1700s diversity. Graphs (a)–(d) were modified from Cooper SR © (1995) Chesapeake Bay watershed historical land use: impact on water quality and diatom communities. *Ecological Applications* 5: 703–723, with permission from American Association for the Advancement of Science.

eutrophication, small cyanobacteria become abundant; in parts of the Florida Keys, for example, the formerly clear water over coral reef areas has become an opaque emerald green from picoplanktonic cyanobacteria blooms. Trace metals such as iron have also been shown to be limiting to phytoplankton growth in some estuarine and marine waters where N and P are at levels that would otherwise be expected to support more algal production.

As eutrophication progresses, the previously described shift in temperate-zone phytoplankton assemblage structure from certain diatoms to other diatom species, flagellates, and cyanobacteria causes subtle but important, undesirable changes for the food web that can adversely affect secondary production. For example, as reviewed by Kilham *et al.* (1997), some diatom species produce high quantities of certain lipids that are essential for zooplankton reproduction. Algal species

Figure 9 The outcome of competition between diatoms for limiting nutrients (silica or PO_4^{3-}) across a gradient of Si : P ratios, comparing two freshwater planktonic diatoms, *Cyclotella meneghiniana* and *Asterionella formosa*, under growth-limiting conditions (temperature, light, and other conditions held constant). These chemostat culture experiments indicate (a) conditions in which *A. formosa* is dominant because it can outgrow *C. meneghiniana* at very low P (as micromolar concentrations or micromoles per liter of phosphate, $\mu\text{M PO}_4^{3-}$), (b) conditions wherein the two species can coexist (circles) because one is limited by P, and the other is limited by Si (as silicon dioxide concentrations, $\mu\text{M SiO}_2$); and (c) conditions wherein *C. meneghiniana* can dominate because it can outgrow *A. formosa* at lower Si. Reprinted from Tilman D (1982) *Resource Competition and Community Structure*. Princeton: Princeton University Press, with permission from Annual Reviews.

that may replace these diatoms under increasingly eutrophic conditions do not produce these lipids, or produce much less of them. Analogous phenomena occur in freshwaters, estuaries, and coastal environments. For example, Starr *et al.* (1990) reported that spawning of green sea urchins (*Strongylocentrotus droebachiensis*) and blue mussels (*Mytilus edulis*) apparently is triggered by a heat-stable metabolite that is released in high abundance by certain phytoplankton, especially certain diatoms such as *Skeletonema costatum* (Bacillariophyceae). This substance is not produced, or is produced in much lower quantities, by flagellate algae that replace these diatoms under cultural eutrophication. Different algal species can also affect zooplankton production and composition because they have different N : P stoichiometry which, in turn, affects the stoichiometry of the grazers.

Harmful Algal Blooms and Anthropogenic Nutrient Enrichment

Among the algal species that thrive in nutrient over-enriched or eutrophying waters are many noxious species such as cyanobacteria that are potentially toxic to zooplankton, fish, and wildlife in freshwaters and certain estuaries (Baltic Sea and Australia), and certain dinoflagellates and other flagellates that are potentially toxic to finfish and shellfish in estuarine and

Figure 10 The outcome of competition among diatoms, green algae, and cyanobacteria (blue-green algae) for limiting nutrients (nitrogen or phosphorus) across a gradient of N : P ratios under silica-replete (nonlimiting) conditions, showing an additional influence of temperature. The comparison includes representative species of freshwater lake diatoms (white circles), green algae (black diamonds), and cyanobacteria (white squares) in chemostat culture under growth-limiting conditions for N and P (but not for Si). Note that at the coldest temperature indicative of conditions during spring and fall seasons in this north temperate lake, the cold-optimal diatoms outcompeted the greens and cyanobacteria across all N : P ratios. That is, temperature, rather than N or P, was the most important condition limiting the growth of green algae and cyanobacteria relative to diatoms. The mid-range temperature represented a transitional area where some growth could occur for species representing each group. The highest temperature favored warm-optimal cyanobacteria (which tend to have high P optima), especially at low N : P ratios when P was more abundant.

Figure 11 The outcome of competition among diatoms, green algae, and cyanobacteria (blue-green algae) for limiting nutrients (phosphorus or silica) across a gradient of P:Si ratios, showing the influence of temperature. The outcome of competition is indicated among freshwater lake diatoms (white circles), green algae (black diamonds), and cyanobacteria (white squares) in chemostat cultures under growth-limiting conditions for Si (needed only by the cold-optimal diatoms) and P at two temperatures. At the lower temperature, cold-optimal diatoms dominated across all Si : P ratios. However, at the higher temperature they were able to dominate over green algae only at high Si : P ratios, when their Si requirements were alleviated by the relatively high Si. The cyanobacteria species were able to outcompete the other groups only at one transitional Si : P ratio, even at the higher temperature which was still suboptimal for the cyanobacteria.

marine coastal areas worldwide (Burkholder 1998, 2009; Burkholder *et al.*, 2008). It has long been recognized that freshwater algae, most notably a wide array of noxious bloom-forming cyanobacteria species, are strongly stimulated by P and also by N pollution. In contrast, intensive study, for many decades, of a small number of harmful marine species that grow in oligotrophic waters largely resulted in a longstanding dogma that harmful estuarine and marine algae generally are not stimulated by nutrient pollution in estuarine and marine habitats. This dogma was finally laid to rest: a landmark paper published by Heisler *et al.* (2008) reported broad scientific consensus that many harmful estuarine and marine algae are indeed stimulated by N and P over-enrichment, and by changes in nutrient forms or their relative availability.

The fact remains that some species of harmful algae are found in oligotrophic habitats and historically have not been thought to be favored by elevated nutrients, and are believed

instead to have optimal growth in low-nutrient conditions. Under low nutrient conditions they would be dependent on rapidly recycled nutrients, as the fundamental requirement of nutrients for cells is generally not different under low-nutrient conditions. Recent studies have provided evidence, however, that certain of these species can be directly or indirectly stimulated by nutrient enrichment. For example, the invasive diatom *Didymosphenia geminata* forms extensive benthic mats in light-replete oligotrophic streams, and its abundance has been negatively correlated with high N and P. However, a series of stream-side experiments conducted by Bothwell and Kilroy (2011) showed that addition of PO_4^{3-} , alone or together with NO_3^- , resulted in a prolonged increase in cell production; thus, the cells of this oligotrophic species divided faster under P enrichment.

As a second example, the potentially toxic dinoflagellate, *Karenia brevis*, causes ecologically and economically damaging “red tides” along the coasts of Florida and Texas, USA. For many years this organism was thought to be a strict phototroph, relying entirely on photosynthesis for its nutrition. Within the past decade, however, *K. brevis* has been found to act as a grazer of the small cyanobacterium *Synechococcus* (Jeong *et al.*, 2005), which is abundant in nutrient over-enriched coastal waters in the Gulf of Mexico. In fact, Glibert *et al.* (2009) reported that *K. brevis* consumed up to 84 *Synechococcus* cells per hour, fulfilling up to 40% of its cellular N requirement, especially under low light. These authors hypothesized that *Synechococcus* blooms may be stimulated by nutrient pollution, in turn providing an additional source of nutrients for enhanced growth of *K. brevis*, and for its red tides to be sustained by grazing the cyanobacterial prey.

Changing nutrient supplies and stoichiometric imbalance from altered nutrient supply ratios have resulted in major, diverse effects on harmful algae, exemplified here by the potentially toxic mixotroph *Prymnesium parvum* (Haptophyta). *P. parvum* blooms generally occur in eutrophic waters that are imbalanced in nutrient supplies and supply ratios relative to unenriched habitats. Cell production can be stimulated by PO_4^{3-} enrichment. In contrast, N or P limitation, as well as certain other stressors and suboptimal conditions, significantly enhance production and release of an array of toxins by this organism. When these toxins are released, they form micelles and apparently require activation by cofactors that can include other dissolved plant nutrients such as potassium, calcium, and magnesium. The nutrient stress connection operates as an after-effect for blooms that develop, in the first place, because of nutrient-rich conditions. The toxins of *P. parvum* include a mix of PO_4^{3-} -containing proteolipids, with hemolytic activity, which are thought to be precursors of structural membrane components, or products of imbalanced cell membrane metabolism. These toxins accumulate within cells during exponential growth phase, and are released into the surrounding medium during stationary phase when growth is limited or stressed. High toxin activity is hypothesized to occur under PO_4^{3-} limitation because formation of phospholipids for membrane synthesis is disrupted, resulting in leakage of cellular metabolites including toxins (Burkholder, 2009, and references therein). Research by Granéli and colleagues (e.g., Granéli and Johansson, 2003) has shown that nutrient stress, in the form of either inorganic P or

inorganic N limitation, significantly increases *P. parvum* toxin production or release.

As additional species of harmful algae are evaluated for their responses to increasing nutrient supplies from cultural eutrophication, it will be important to consider that the concentration of a nutrient at any given time may not be correlated with its actual bioavailability, because many phytoplankton can grow for up to several generations on internally stored "luxury-consumed" nutrient pools. Moreover, harmful algal blooms can sometimes develop in regions that are spatially displaced (e.g., downstream) from nutrient sources, partly because as nutrients move through aquatic systems, they are recycled and transformed to forms that are more readily available for algal use. This phenomenon has sometimes made it difficult to link blooms with the upstream nutrient sources. Major progress will continue to be made in understanding the complex direct and indirect influences of nutrient enrichment in harmful algal blooms by studying additional species to characterize their luxury consumption and subsequent use of inorganic N, P, and C under changing nutrient stoichiometry as their habitats become more eutrophic; their cell budgets for these nutrients; and their reliance on mixotrophy as well as photosynthesis to meet their nutritional needs.

Microbial Heterotrophs in Low-Light Environments

Algae and other phototrophs are common "first responders" to nutrient enrichment, and eutrophication has sometimes been defined as an increase in organic carbon to an aquatic ecosystem caused by primary productivity. This definition is too restrictive, however, because increased organic carbon from nutrient pollution is not always a result of primary productivity. The distinction is important because it means that nutrient pollution can detrimentally affect beneficial aquatic life through means other than increase algal growth. For example, from an analysis of blackwater streams in the Southeast, Mallin *et al.* (1993, 2005) reported that within-stream heterotrophic (bacterial) processes, stimulated primarily by P and secondarily by N enrichment, were the major influences on BOD. Blackwater systems generally do not provide sufficient light to enable algae to proliferate in response to nutrient enrichment. However, humic materials in the blackwater can alter nutrient biogeochemistry, generally sequestering nutrients but sometimes also making favored nutrients more available.

Macroalgae

Freshwater Communities

Macroalgae are the major flora of the littoral zones of some lakes, and of many shallow estuarine and marine waters, and they include some notorious 'aquatic weeds' that respond to cultural eutrophication. Temperate-zone freshwater and oligotrophic hardwater lakes may contain abundant benthic charophytes and, rarely, a few species of small brown macroalgae (Heterokontophyta). Oligotrophic softwater lakes can have populations of small, benthic red macroalgae

(Rhodophyta), especially near spring-fed areas with bubbling carbon dioxide. As eutrophication progresses, populations of certain filamentous green algae and cyanobacteria that would otherwise be considered as microalgae develop visual biomass accumulations, especially under high P enrichment and also under N enrichment. For example, *Cladophora glomerata* (Chlorophyceae) forms masses of long hair-like growth, and cyanobacteria (e.g., *Anabaena*, *Aphanizomenon*, *Microcystis*, *Plectonema wollei*) form tufts or amorphous masses of greenish, bluish-green, or reddish gray slime.

Macroalgae are the dominant autotrophs of mid-order streams where hard substrata are available for colonization and light is moderate to high, especially after leaf fall in colder seasons. Stream-inhabiting macroalgae are often much more diverse and abundant than lake macroalgal floras. Nutrient-poor (often softwater) stream segments are colonized by diverse, abundant cold-optimal algae such as the diatom *Eunotia pectinalis*; the heterokontophyte *Tetrasporopsis*; chlorophytes such as *Spirogyra*, *Tetraspora*, and *Oedogonium*; red algae such as *Batrachospermum* and *Paralemanea*; and cyanobacterial mat formers like *Phormidium* spp. (for example, see Sheath and Burkholder (1985)). As eutrophication progresses, softwaters may develop larger populations of filamentous green algae such as certain species of *Oedogonium* and *Mougeotia*, or dense growth of colonial *Hydrodictyon* and *Stigeoclonium*. The latter taxon is also known to tolerate high metal concentrations that may be found in poorly treated sewage. Hardwater streams under high P enrichment, as well as the littoral zones of hardwater lentic systems, commonly become choked with massive growth of *Cladophora* spp. where light is sufficient for their proliferation (see Oligotrophication – Reversing the Impacts of Eutrophication? below, for information about the famous case of *Cladophora* in the lower Laurentian Great Lakes).

Estuarine and Marine Communities

Macroalgae also dominate the flora of many shallow estuaries, lagoons, and upper embayments, coral reefs, and rocky intertidal/subtidal habitats. Nutrient enrichment leads to reduction in the diversity of macroalgae and associated fauna. Opportunistic species of green algae within the genera *Ulva* (also found in saltwater lakes such as the Great Salt Lake of Utah) and *Cladophora*, and within the brown algal genus *Ectocarpus*, have rapid growth rates and proliferate because they can more quickly take advantage of the elevated nutrient levels and shade out other species. Repeated, pulsed nutrient enrichment to temporarily elevated levels – characteristic of many eutrophic waters – encourages these rapidly growing species, whereas more slowly growing, perennial species tend to store large quantities of nutrients (e.g., N). Macroalgal overgrowth in brackish/marine habitats commonly has been related to elevated N_i (e.g., Lapointe, 1997; Lapointe *et al.*, 2005). NH_4^+ is more readily used (less energetically costly) than NO_3^- , but either N_i form has significantly stimulated growth of opportunistic macroalgae in field research and mesocosm experiments. PO_4^{3-} can also stimulate macroalgal growth when N is abundant.

For example, in Boston Harbor, Massachusetts, USA, sea lettuce (*Ulva*) formed dense populations for many years near outfalls of poorly treated sewage. The massive seaweed growth

reduced water flow, smothered shellfish, and affected shoreline areas with an intolerable stench of hydrogen sulfide from decomposition of senescent or dead material. In the Peel–Harvey Estuary, Australia, dense mats of green macroalgae and cyanobacteria have developed in response to P loading. In seagrass meadows worldwide, such overgrowth has been documented to reduce light and promote declines in various seagrass species (Burkholder *et al.*, 2007, and references therein). Along the intertidal area of the Baltic Sea, sewage inputs have been related to overgrowth of formerly dominant brown seaweeds (*Fucus* spp.) by opportunistic macroalgae.

In subtidal outfalls, nutrient enrichment from sewage and other wastes has stimulated overgrowth by ‘weedy’ red algae such as certain species of *Polysiphonia*. The red alga *Laurencia poiteaui*, the green alga *Cladophora fuliginosa*, and the brown alga *Cladosiphon occidentalis* proliferated over seagrass beds in eutrophying sewage-influenced areas of Florida Bay, USA, with maximal biomass at ~300 g dry weight per square meter. The exotic green macroalga *Caulerpa taxifolia* is a subtidal, subtropical weed that has invaded colder waters of the Mediterranean, and sewage appears to further stimulate its robust growth. This organism can produce metabolites that discourage predation; sea urchins typically avoid consuming *C. taxifolia* and starve to death if it is the only available food. Subtidal forests of giant kelp (*Macrocystis pyrifera*) died back and failed to reproduce during the 1960s–1970s near outfalls of sewage discharged from Los Angeles. The kelp bed loss apparently resulted from toxic substances in the poorly treated sewage.

Sensitive oligotrophic coastal marine coral reefs have been overgrown and smothered by macroalgae after nutrient input from sewage. In Kaneohe Bay, Hawaii, for example, phytoplankton near sewage outfalls first removed the N_i , and were transported to the central area of the coral reef where they decomposed and released N_i for stimulation of the opportunistic green macroalga, *Dictyosphaeria cavernosa*. Inorganic nutrient concentrations are frequently below detection in natural coral reef waters. Lapointe’s (1997) research indicated that even minor sewage-related increases in N_i ($> 1 \mu M$) and P_i (0.1 – $0.2 \mu M$ SRP) off the coast of Jamaica, together with decreased herbivory from natural and fishing-related disturbance, were sufficient to stimulate blooms of the green eutrophic indicator macroalga, *Chaetomorpha linum* and cyanobacteria that have overgrown coral reefs in that area.

Reduced light from such excessive nutrient-stimulated macroalgal (and sometimes phytoplankton) growth affects coral growth by decreasing the productivity of zooxanthellae, symbiotic photosynthetic dinoflagellates inside the coral tissue, that provide much of the corals’ nutrition. Nutrient over-enrichment can also shift species dominance within the coral community. As the corals are out-competed for space, filter-feeding taxa such as sponges may be stimulated by increased phytoplankton food resources, and replace corals as dominant species. Sedimentation of decomposing phytoplankton, and other disturbances such as destructive techniques for fish harvesting, can exacerbate the impacts of cultural eutrophication on coral growth and survival.

Macrophytes, Aquatic Vascular Plants

Freshwater Communities

Floating, submersed, and emergent aquatic vascular plants, commonly called macrophytes, respond to nutrient enrichment differently because the competitive forces that they encounter vary with plant growth habit. *Rooted plants* – including those with specialized floating leaves, submersed growth, or emergent growth – generally do not compete with phytoplankton and other algae for nutrients, because they obtain most nutrients (except carbon, usually taken from the water) from the nutrient-rich sediment, with leaf uptake of nutrients from the less enriched overlying water as a secondary nutrient source. In contrast, floating plants at the water surface, such as the Lemnaceae (duckweed family) and the exotic weed *Eichhornia crassipes* (water hyacinth), must compete with suspended algae for N and P, but rely on the overlying air for their carbon. Floating submersed plants must compete with suspended algae for all major nutrients. They tend to have well-developed root systems to aid in nutrient acquisition, and in shallow waters with sparse open-water habitat, they can outcompete phytoplankton for light by forming dense surface populations that reduce or eliminate light availability in the underlying water. SAV is usually eliminated in highly eutrophic systems primarily through light reduction by phytoplankton and other algal overgrowth, as described by Phillips *et al.* (1978) and Wetzel (1978, 2001).

Like stream-inhabiting macroalgae, rooted macrophytes in river systems reach maximal abundance and species diversity in midorder segments. But, in contrast to lake-inhabiting macroalgae, submersed freshwater macrophyte communities attain highest species richness and abundance in mesotrophic lakes, often with dominance by *Potamogeton* spp. The native macrophyte beds help to decrease turbidity from incoming suspended sediments by slowing water motion and trapping sediment particles; their root systems also help to stabilize the lake bottom and reduce sediment resuspension. Light plays a major role in progressive SAV decline as lakes become increasingly eutrophic. In early stages of eutrophication, nutrient enrichment can stimulate macrophyte growth through luxury uptake and tight recycling, sometimes without an increase in phytoplankton. Over time, however, epiphytic algae take advantage of the greatly increased surface area for colonization afforded by the macrophytes, and they can both severely shade the underlying plants and restrict their carbon acquisition.

Increased epiphyte production stimulates growth of invertebrates and, in turn, can lead to increased abundance of cyprinids (e.g., bluegill sunfish – *Lepomis macrochirus*) and other invertebrate-feeding fish. These fish can reduce zooplankton densities, which relieves grazing pressure on phytoplankton that, in turn, proliferate and cloud the water so that light becomes yet more limiting for the macrophytes beneath. Under accelerated eutrophication, dramatic declines in native macrophyte populations typically occur over a relatively short period (several years). The loss of most native submersed macrophytes is often a critical turning point in the eutrophication of a lake or estuary. Without the habitat that provided cover for fish and substrata for littoral-zone invertebrates, cyprinid fish increase their grazing pressure on zooplankton, and their removal of zooplankton effectively decreases grazing

pressure on the phytoplankton. The increased anoxic/hypoxic conditions from yet-higher phytoplankton production cause further reductions in benthic invertebrate species and abundance, leading to more intense cyprinid grazing pressure on zooplankton. Thus, highly eutrophic lakes contain dense phytoplankton and food-limited (stunted) cyprinids.

Emergent macrophytes at the littoral fringe of lakes, rivers, estuaries, and marine coasts can maintain enhanced growth and biomass over a wide range of nutrient inputs. Under certain conditions with sustained high nutrient loading, however, emergent macrophytes can decline. The nutrients stimulate increased growth, greater stem density and, often, accelerated longitudinal growth, leading to higher intraspecific competition for light and weakening of stems. The elevated nutrients also promote higher suspended algal growth as well as higher growth of epiphytes on the submersed portions of the macrophyte stems. The increased weight makes the plants less well anchored, leading to dieback at the water's edge. Elevated N_i also promotes reduction in supporting vascular tissues, and loss of stem strength.

Estuarine and Marine Communities

Brackish waters are colonized by rooted, mostly freshwater species with moderate salt tolerance (as examples, certain *Potamogeton* spp., *Valisneria americana*, *Zanichellia*). In such habitats, light is often the primary resource limiting growth. Species with broader salt tolerance such as *Ruppia maritima* also can be abundant. Only about 50 species of angiosperms, mostly close relatives of freshwater *Potamogeton* spp., have the salt tolerance needed to thrive in marine habitats. Nearly all of these seagrasses grow in muddy substrata of shallow coastal lagoons and quiet embayments. Estuarine and marine macrophytes tend to be highly sensitive to light reduction and, thus, susceptible to eutrophication-related turbidity from algal (phytoplankton, epiphyte, and macroalgae) overgrowth and sediment loading/resuspension. Such shading causes gradual dieback and loss of most SAV, leading to dramatic declines, in turn, in the diversity and abundance of many species that depend on the habitat provided by these plants.

More sensitive SAV species are replaced by others that are tolerant to eutrophic conditions – for example, among subtropical seagrasses, field observations and limited experiments have indicated that turtle grass (*Thalassia testudinum*) is more sensitive to eutrophication than shoal grass (*Halodule wrightii*) and manatee grass (*Syringodium filiforme*). Other regions may not have additional seagrass species available to replace more sensitive species and, even where such species are present, they typically offer less desirable fish nursery habitat than the former dominant. Thus, in seagrass meadows under nutrient over-enrichment, more oligotrophic seagrass species are replaced by less sensitive species when available. As eutrophication progresses the seagrasses are eliminated, and rapidly growing macroalgae and phytoplankton become the dominant flora.

Although light reduction is considered the major mechanism for seagrass decline under cultural eutrophication, excessive nutrients can act independently of light to promote seagrass loss (Figure 12). The dominant north temperate species, eelgrass (*Zostera marina*), apparently lacks a physiological mechanism to inhibit NO_3^- uptake through its leaves,

Figure 12 The effects of water-column NO_3^- enrichment and light reduction on shoot production of the seagrass, *Zostera marina*. From the first author's outdoor mesocosm experiments, indicated as the percent decrease from shoot production of control plants that did not receive water-column NO_3^- additions or light reduction (except that plants in controls and treatments all received an additional 30% light reduction for 3 h at 09.00, 12.00, and 15.00 h on a 3-day rotation using neutral density screens to stimulate conditions during high tide). Treatments were imposed for 10 weeks during the fall growing season for *Z. marina*. Controls were maintained at ambient natural light (except during simulated high tide) and NO_3^- ($<30 \mu g NO_3^- N l^{-1}$). Treatments included low N (at $50 \mu g NO_3^- N l^{-1}$, or $3.5 \mu M NO_3^- N$) and high N (at $100 \mu g NO_3^- N l^{-1}$, or $7 \mu M NO_3^- N$; low and high NO_3^- additions were added in the morning as a pulse of enrichment) at each of three imposed light levels as 30, 50, or 70% reduction of ambient surface light (I_0 , accomplished using the neutral density screens, with additional shading to simulate high tide as noted). Water exchange (5–10% of the tank volumes per day replaced with fresh estuarine water) was done in late afternoons; see Burkholder et al. (1992), for further details about the mesocosm system. In all treatments with water-column NO_3^- enrichment, *Z. marina* declined in shoot production relative to shoot production of control plants, and the NO_3^- inhibition effect was exacerbated by light reduction (means ± 1 standard error; $P < 0.05$, $n = 3$ mesocosms for controls and 3 for each treatment). These effects were not caused by algal overgrowth, which was maintained at low levels in controls and all treatments throughout the experiment.

as indicated by the research of Roth and Pregall (1988) and Burkholder et al. (1992). Most plants take up NO_3^- during the day with the energy from photosynthesis. In contrast, *Z. marina* takes up water-column NO_3^- day or night if it becomes available, as shown by Touchette and Burkholder (2000) (Figure 13). This species is thought to have evolved in N-poor coastal waters, and sustained NO_3^- uptake under temporary enrichment may have developed as a once highly advantageous competitive mechanism or "strategy". However, as coastal waters have become more eutrophic from sewage, septic effluent leachate, agricultural sources, and other anthropogenic sources, sustained uptake of water-column NO_3^- likely has become a disadvantage. NO_3^- enrichment of the sediments, under control by an abundant microbial

Figure 13 The response of the seagrass, *Zostera marina*, to pulsed water-column NO_3^- enrichment in light and dark periods. Plant NO_3^- uptake is indicated as leaf activity of the enzyme (nitrate reductase (NR), used to actively take up NO_3^-) of previously unenriched shoots (means ± 1 standard error). A spike of NO_3^- ($110 \mu\text{g NO}_3^- \text{N l}^{-1}$) was added in the morning (white arrow) or, to a subsample of plants from the same population, at night (black arrow). NR activity (plotted as micromoles of nitrite product produced per gram dry weight of plant leaf tissue per hour) indicated that *Z. marina* took up NO_3^- day or night, whenever a pulse was detected. In fact, maximal NR activity was significantly higher when NO_3^- was added during the dark period. Reprinted from Touchette BW and Burkholder JM (2000) Overview of the physiological ecology of carbon metabolism in seagrasses. *Journal of Experimental Marine Biology and Ecology* 250: 169–205.

consortium, does not cause a similar effect and, instead, can be mildly stimulatory.

NO_3^- uptake is a metabolically expensive process, requiring high cellular energy. Research by Touchette and Burkholder (2000) indicated that sustained water-column NO_3^- uptake by *Z. marina* can promote severe internal carbon imbalances, apparently from the need to shunt C skeletons from photosynthesis for use in high amino acid synthesis to prevent internal accumulation of toxic products such as NH_3 . The physiological mechanism of an internal “carbon drain” from sustained NO_3^- uptake was earlier documented for algae by Turpin *et al.* (1991). A common trait of *Z. marina* shoots under excessive water-column NO_3^- enrichment is structurally weakened growing regions, perhaps analogous to the above-mentioned loss of stem strength that has been reported in certain freshwater emergent macrophytes under NO_3^- enrichment. Excessive N_i enrichment has also promoted seagrass attack by pathogens (e.g., the slime mold *Labrynthula zosterooides*), hypothesized to occur because N and C are internally shunted to amino acid production rather than to production of alkyls and other antimicrobial compounds.

Another seagrass that has been examined for the NO_3^- inhibition phenomenon, *Halodule wrightii*, and certain macroalgae (e.g., *Ulva lactuca*) have shown depressed growth in response to NO_3^- enrichment, although at much higher N levels (ca. $1.4 \text{ mg NO}_3^- \text{N l}^{-1}$, pulsed daily for 4–5 weeks) than for *Z. marina* ($50\text{--}110 \mu\text{g NO}_3^- \text{N l}^{-1}$, pulsed daily for 5–8 weeks). *Ruppia maritima* has been experimentally stimulated by high water-column NO_3^- but inhibited by elevated N_i as NH_4^+ ; and *Z. marina* has been experimentally inhibited by high NH_4^+ levels, as well. In mesocosm experiments, light reduction has been shown to exacerbate the inhibitory effects

of water-column NO_3^- enrichment on shoot production in *Z. marina*. Warm temperatures exacerbate water-column NO_3^- enrichment impacts on root growth of *Z. marina*, as well, suggesting that warming trends in climate change may be expected to interact with eutrophication to adversely affect this beneficial habitat species.

Invasive macrophytes such as *Hydrilla verticillata* (hydrilla) or *Egeria densa* (Brazilian elodea) are also a concern in ecosystems that have been altered by nutrient loading. These plants appear to be most common in systems that have received excessive N loading relative to P, or systems in which P has been removed but N loads remain high. Examples of ecosystems invaded by these plants after P removal include the Potomac River, a tributary of Chesapeake Bay, and the San Francisco Bay Delta. Both systems receive (or historically received) high nutrient loads from sewage discharge, but have sustained reduced P loading due to improved effluent treatment and removal of P from laundry detergents. Highly productive invasive plants like *H. verticillata* and *E. densa*, have been characterized by Yarrow *et al.* (2009) as “ecological engineers.” They can thrive in turbid waters but also tend to trap sediments, thereby reducing turbidity. They also provide habitat for zooplankton and fish, and through their productivity, they alter pH and both water-column and sediment nutrient chemistry.

Microfauna

Freshwater Communities

Whereas plants and mixotrophic algae respond directly to nutrient enrichment, animals are generally indirect recipients

of eutrophication impacts. Nevertheless, all are significantly affected by nutrient control of the quality (including size, taste, and ease of filtering) and quantity of their algal, bacterial, or detrital food (Harper, 1992). Freshwater zooplankton consist of three main groups: protozoa (mainly ciliates and flagellates) and rotifers form the microzooplankton (maximum dimension *ca.* 45 μm to less than 70 μm); and crustaceans form the macrozooplankton (mainly cladocera, calanoid, and cyclopoid copepods, *ca.* 70 μm to less than 500 μm).

Protozoa diversity and abundance increases with the amount of available organic matter that becomes directly or indirectly available through eutrophication, until the fauna are restricted by low-oxygen conditions. Oligotrophic protozoan plankton can be dominated in number by small-bodied ciliates, whereas large ciliates can contribute most of the biomass (especially members of the Oligotrichida such as *Plagiopyla nasuta* and *Paramecium trichium*). Mesotrophic and eutrophic lakes are more commonly dominated in both number and biomass by small-bodied species (e.g., member of the Scuticociliatida). Protozoans are relatively sparse in oligotrophic lakes in comparison to the species-rich and abundant fauna that develop in moderately eutrophic waters. Aggregates of bacteria and detritus form in the water column as organic materials decompose, and these microhabitats can support protozoa that rival shallow benthic communities in diversity. Subtropical lakes show similar trends, but have been reported to support higher ciliate abundance and diversity at a given trophic status than temperate lakes.

Heterotrophic flagellates in the water column are bacterivores, whereas larger ciliates and heliozoa commonly prey on mixed populations of heterotrophic and autotrophic flagellates, and other algae. In low-oxygen waters, heliozoan amoebae and ciliates such as *Coleps* and *Euplotes* retain endosymbiont green algae (zoochlorellae) that photosynthesize and generate oxygen for their hosts. As nutrient enrichment increases, bottom waters and surface sediments become more organically enriched, but the physiological demands on protozoans and other microfauna such as certain rotifers are greater. Survival generally depends on tolerance of low-oxygen and often co-occurring acidic conditions. In organically overloaded, hypoxic sediments, protozoa species diversity is very low relative to that in well-aerated sites. Bacteria and dissolved organic matter form the major food sources, consumed by species such as *Paramecium*, *Chilomonas*, and *Astasia*. Anoxic sediments become colonized by specialized protozoa such as pelobionts and diplomonads, as well as certain ciliates and amoebae.

Rotifers include many algal herbivores as well as detritivores and a few carnivorous species. They generally attain highest species diversity and abundance with increasing small-celled phytoplankton in moderately eutrophic lakes and lower rivers. These microzooplankton generally are favored in abundance over macrozooplankton under increasing eutrophication. However, rotifer species diversity declines as eutrophication progresses to dominance of the phytoplankton by cyanobacteria, especially large mucilaginous colonial species that clog the filtering apparatus of the animals. Rotifers can be adversely affected, as well, by the toxins from certain cyanobacteria that are seasonally characteristic of eutrophic lakes.

Among macrozooplankton in freshwaters, cyclopoid copepods (raptorial feeders) generally feed most efficiently on larger particles (e.g., algae with biovolume $\leq 1000 \mu\text{m}^3$), whereas calanoid copepods consume particles $\leq 100 \mu\text{m}^3$, and cladocerans eat small particles at *ca.* $10 \mu\text{m}^3$. Changes in biodiversity under cultural eutrophication depend, in part, on differences among these species in efficiencies of feeding at certain particle (algal or detrital) concentrations and size ranges, and in the responses of life history stages to food limitation. Changes in biodiversity under eutrophication can also result from fundamental differences in the nutrient stoichiometry required to make the biomass of one type of organism compared to another. Cyclopoid copepods and cladocerans, for example, are generally more P-rich in their biomass than calanoid copepods. Nutrient enrichment alters food particle size and abundance which, in turn, leads to competitive species displacement. Larger-bodied individuals are often more efficient filter feeders than smaller fauna. However, larger species may not be competitively superior because their juveniles tend to be more vulnerable to food limitation than adults of smaller species. Smaller species withstand food depletion by reducing metabolism, growth, and egg production. Moreover, their specific food ingestion rate (milligrams food ingested per milligram of zooplankton biomass) is usually higher than that of larger zooplankton.

Calanoid copepods (e.g., *Eudiaptomus*) often dominate the microfauna of oligotrophic and mesotrophic lakes. These organisms feed efficiently on larger algal cells in those systems, with higher ingestion efficiencies at low food density. As algal prey densities increase under eutrophication, larger cladoceran species become abundant under low to moderate predation by fish, whereas high predation tends to select for smaller cladocerans such as *Bosmina* and *Ceriodaphnia* over *Daphnia*. The larger cladoceran species tend to have higher population growth rates than calanoid copepods. Their population cycles during warmer months have been shown to be mainly controlled by the relative proportions of edible and inedible algae, temperature, and predation. Like rotifers in the presence of abundant food, cladocerans can reproduce parthenogenically, thus allowing for rapid growth rates. They are considered more efficient filter feeders at moderate to high algal densities because they ingest more food for the same amount of energy expended, relative to ingestion under food-limited conditions.

Macrozooplankton biomass increases under eutrophication in both temperate and tropical lakes, with increasing dominance by small-bodied species. High-efficiency bacterial feeders are selected for, as bacterial abundances increase under accelerated eutrophication. However, abundant co-occurring cyanobacteria with copious mucilage clog the filtering apparatus of large-bodied microzooplankton. Moreover, some cyanobacteria are directly toxic to these fauna. In highly eutrophic lakes, the more selective feeding of calanoid copepods, and the seizing behavior of herbivorous cyclopoid copepods, may afford one or both groups a competitive advantage. Smaller cladocerans such as the littoral-zone chydorid *Chydorus* may become abundant during dense cyanobacteria blooms because of their high efficiency in filtering the extremely small, solitary eubacteria and cyanobacteria particles associated with the blooms while being able to avoid filter apparatus clogging

by large and mucilaginous cyanobacteria colonies. Eutrophication can cause other impacts on zooplankton species, apart from changes in the available food. For example, as bottom waters become increasingly hypoxic, survival is depressed for zooplankton eggs that sink to the bottom as part of the life cycle. Thus, nutrient enrichment can impair zooplankton recruitment as an indirect effect.

Estuarine and Marine Communities

Impacts of anthropogenic nutrient loading have been more difficult to generalize from the complex flow/water exchange environments of estuaries and from large-scale marine environments with high physical and biological variability. Nevertheless, substantial progress has been made in the past two decades in understanding the effects of cultural eutrophication on estuarine and marine fauna (Figure 14). Analyses by Michell (1999) and others have indicated that nutrients generally enhance phytoplankton biomass and carnivores depress herbivore biomass. The strength of the couplings between trophic levels (e.g., phytoplankton and zooplankton) varies, and is strongest in more poorly flushed or closed systems such as upper embayments and coastal lagoons.

Brackish and marine habitats differ from freshwaters in having fewer rotifers or cladocera, more extensive representation by protozoans (especially ciliates and foraminiferans), and often-abundant planktonic nauplii (young life history stages) of sessile adult fauna ranging from molluscs and

malacostracan crustaceans to vertebrates. Holoplankton spend their entire lives in the water column. Among these are microzooplankton including larval forms of certain macrozooplankton, as well as tintinnid and nonloricate ciliated protozoans, heterotrophic flagellates, and amoebae. In benthic habitats, the 'meiofauna' (similar in size to microzooplankton) include nematodes, harpacticoid copepods, many turbellarians, and several minor phyla with diverse feeding habits and life styles, mostly consumers of other microbes as prey. Macrozooplankton include calanoid copepods, especially of the genus *Acartia*, cyclopoid copepods and planktonic harpacticoids, and non-copepod crustaceans (especially carideans and mysids) and chaetognaths (arrow worms). Meroplankton, which spend only part of their lives in the plankton as larval stages, may include immature forms of benthic invertebrates and tunicates; eggs, larvae, and juveniles of shrimp, crabs and fish; and sexual stages of hydrozoan and scyphozoan cnidarians (jellyfishes).

The microzooplankton are among most important herbivores on phytoplankton among estuarine and marine zooplankton and, thus, are strongly influenced by changing phytoplankton food quality and abundance under eutrophication, with trends that are somewhat analogous to those described for freshwater microzooplankton. Zooplankton species diversity is highest in moderately nutrient-enriched waters, but significantly declines as nutrient enrichment becomes more excessive with accompanying shifts to dominance of unpalatable algal species and pronounced bottom-water oxygen deficits. For example, in the Peel-Harvey Estuarine

Figure 14 Comparative evaluation of fishery response to nutrients based on data from around the world. Each curve represents a natural guild of species and their reaction to increasing nutrient supplies. The vertical dotted lines separate general categories of organic production that result from different levels of nutrients. Modified from Diaz RJ (2001), Figure 1, who modified and redrew the original figure from Caddy's (1993) model relating fish yield to nutrients supplied to estuarine and marine ecosystems (Caddy J (1993) Toward a comparative evaluation of human impacts on fishery ecosystems of enclosed and semi-enclosed seas. *Reviews in Fisheries Science* 1: 57–96).

System of Australia, large populations of calanoid copepods *Sulcanus* and *Gladioferans* grazed winter diatom blooms, but were rapidly eliminated when the noxious (potentially toxic) filamentous cyanobacterium, *Nodularia spumigena*, became abundant (McComb and Lukatelich, 1995). Predation of carnivorous macrozooplankton by planktivorous fish such as menhaden (e.g., young life history stages of Atlantic menhaden, *Brevoortia tyrannus*) can locally favor small-bodied zooplankton. Such fish become more abundant in localized areas such as small tributaries and are known to track plankton blooms. Later in the growing season these fish switch to phytoplankton prey and, thus, directly compete with herbivorous zooplankton for food resources.

Under high nutrient enrichment, changes in food quality/availability also adversely affect larval stages of many species represented in the meroplankton. Tunicates can increase at the expense of planktonic crustacea, and gelatinous meroplankton (cnidarians, especially jellyfish) can increase at the expense of fish. Jellyfish are favored under increasing eutrophication (Vasas et al., 2007). They are predators on zooplankton and juvenile fish, and are avoided by most pelagic fish, which do not consume them. Low-oxygen conditions in bottom-water habitat decrease survival of zooplankton eggs, and of eggs and larvae of many meroplankton species that settle to the bottom sediments as part of their life cycle.

Invertebrate Macrofauna

The freshwater zoobenthos or bottom macrofauna (>0.5 mm, or 500 μm) consist mostly of insect larvae (with terrestrial adult stages), crustacea, worms, and molluscs. Eutrophication in the littoral zone of lakes and rivers, with accompanying organic pollution, causes similar impacts on the invertebrate macrofauna of these systems. In early stages of eutrophication, oligochaetes, chironomids, gastropods, and sphaeriids increase, and mayfly nymphs such as *Hexagenia* decrease (Harper, 1992). As eutrophication continues, the major pattern with progressive hypoxia/anoxia in overlying waters and surface sediments is the decline and then disappearance of additional oxygen-sensitive species such as stoneflies (*Diura*) and certain taxa of mayfly nymphs (e.g., *Baetis*, *Rhythrogena*) as well as certain caddisfly larvae (e.g., *Rhyacophila*, *Hydropsyche*) and bivalve molluscs.

Eutrophication increases organic matter and bacterial decay, and depresses oxygen concentrations while increasing settlement of organic detritus to benthic organisms such as certain flatworms (e.g., *Polycelis*) that use it for food. In the profundal sediments underlying deeper waters of lakes, the macroinvertebrate biomass increases but is comprised of low oxygen-tolerant species such as certain chironomid larvae and oligochaete worms (e.g., the oligochaete *Tubifex tubifex* which, in one study, survived, grew, and reproduced under continuous hypoxia/anoxia for 10 months). The species diversity of tubificid oligochaetes decreases with advanced eutrophication and organic enrichment, and associated oxygen deficits. However, if oxygen is periodically available, the rich food supply in combination with the lack of more oxygen-sensitive competitors allows robust growth. Declines in chironomid communities occur most rapidly in the change between

nutrient-poor to moderately nutrient-enriched (mesotrophic) waters; and numbers of oligochaetes relative to chironomids increase as organic enrichment increases. In the intermediate zone between the littoral and profundal, the increased supply of fresh littoral detritus is consumed by large-bodied detritivores such as the bivalve mollusc *Dreissena*.

Estuarine and marine coastal invertebrate macrofauna, including molluscs, polychaetes, decapods, and other crustacea, and nemerteans, spend their adult lives buried beneath the sediment surface. They are highly diverse in food acquisition as filter feeders, nonselective deposit feeders, selective deposit feeders, or raptorial/other predators, making generalizations difficult. Increasing organic matter from accompanying nutrient enrichment tends to cause similar impacts as in freshwater systems, namely, an increase in macroinvertebrate abundance under moderately eutrophic conditions, and a decline in species diversity and abundance as eutrophication and associated hypoxia/anoxia progress. Organisms that burrow into anaerobic sediments must be able to gain access to oxygen in the overlying water. Increasing eutrophication leads to elimination of burrowing organisms as the anaerobic zone moves closer to the sediment surface. In highly over-enriched areas, only worms such as *Capitella* may survive. Oxygen does not need to be completely absent for damage to occur – hypoxic waters with 3.0–4.3 mg DO l^{-1} have been related to mortality of some benthic invertebrate species, and to loss of habitat for some shellfish species that require higher oxygen availability.

Changes in food quality and quantity also can reduce the species diversity and abundance of estuarine and coastal marine invertebrate macrofauna under highly eutrophic conditions. For example, an extensive early study by Filice (1959) in San Francisco Bay demonstrated that in domestic sewage outfall areas, few species survived. Species diversity was higher but still depressed in surrounding areas that received dilute sewage. However, in those areas, some species (e.g., the clams *Gemma gemma*, *Mya arenaria*, and *Macoma inconspicua*; the polychaete worm *Polydora uncata*, and the barnacle *Balanus improvisus*) apparently took advantage of new energy and material resources, and became highly abundant relative to their abundance in controlled areas without sewage influence. More recently, an extensive analysis by Glibert (2010) and Glibert et al. (2011) examined major trophic shifts, from phytoplankton composition to mid-trophic levels to fisheries, in the San Francisco Bay Delta over the past ca. 30 years. This analysis related the major trophic shifts to significant alterations in N:P ratios that especially resulted from ammonium-enriched sewage discharges. These changes included apparent significant effects on food quality for various fauna. In the Great South Bay complex of Long Island, New York, previously mentioned duck farms along the bay tributaries fertilized the water with nutrients and organic wastes, and stimulated dense blooms of the small algae, *Nannochloris* sp. and *Stichococcus* sp. (>10⁶ cells ml^{-1}). These algae were very different from the previous phytoplankton assemblage in the area, which consisted of mixed species that are needed to support oysters. Following these changes, oyster populations significantly declined because they were unable to thrive on a diet consisting only of these small algae.

Vertebrate Macrofauna

Cultural eutrophication initially reduces and then eliminates sensitive lake fishes (e.g., salmonids and coregonids), by eliminating oxygen-replete, colder bottom-water habitat, and well-oxygenated spawning areas (Harper, 1992). Fish can avoid low-oxygen waters, but the cold-optimal species encounter warmer waters as they are forced to move from deep areas into the shallows. Most temperate-zone fishes breed in the littoral. Their eggs are more vulnerable to developing short-term (e.g., nightly) oxygen deficits, and to the low-oxygen micro-environment of the increased detritus. Thus, the critical habitat of these sensitive species is destroyed by nutrient over-enrichment, and spawning and recruitment are depressed. Overall, nutrient enrichment generally increases fishery yields to a certain level, but beyond that level fish production declines.

Analogous impacts occur in rivers and estuaries. For example, in parts of the Baltic Sea, cod eggs laid in well-oxygenated surface waters die when they sink to anoxic bottom waters (Diaz, 2001). Oxygen levels in the bottom waters of the Baltic's deep basins are negatively correlated with juvenile codfish abundance. Hypoxia in estuaries has been linked to depressed survival of larval fish, mortality of certain benthic invertebrates used as fish prey, and loss of habitat for mobile species of finfish such as cod that require high oxygen availability. Hypoxia/anoxia represents a growing problem for many estuaries and coastal marine waters, such as the Chesapeake Bay, the Baltic Sea, the Black Sea, the Pamlico Estuary, Long Island Sound, the North Sea, and the Gulf of Mexico by the mouth of the Mississippi River.

The composition of fish communities also changes as the water-column nutrient stoichiometry changes. In addition, planktivorous fish generally differ from demersal (bottom-dwelling) or piscivorous fish in their nutrient stoichiometry. For example, making bone is a P-requiring process; cyprinid fishes are bonier and thus require more P relative to small, planktivorous fish. Thus, nutrients can have both direct (mediated through the food web) and indirect effects on fishes.

Overall population sizes and biomass of fish usually increase with nutrient over-enrichment, often regarded as a beneficial effect in early to mid-stages of eutrophication. However, dominance shifts – for example, in freshwaters the community changes from species such as lake trout to cyprinids, bullheads (*Ictalurus* spp.), and other coarse fish that can tolerate low oxygen concentrations (Figure 15). In lakes with well-developed littoral zones of rooted aquatic vegetation, high predation pressure from piscivorous fish such as largemouth bass (*Micropterus salmoides*) or pike (e.g., *Esox lucius*) maintains low biomass of cyprinid fish and, thus, low predation pressure on large-bodied zooplankton. These large zooplankton, in turn, control phytoplankton biomass through strong grazing pressure, so that there is high visibility for visually feeding piscivorous fish, and abundant light for macrophyte growth.

As eutrophication progresses, the littoral-zone macrophytes disappear and the carrying capacity of the system for piscivorous fish is reduced. Thus, (zoo)planktivorous fish are freed from high predation. Their larvae tend to selectively feed on the largest herbivorous zooplankton species (based on the

Figure 15 Trends in fish yields and taxonomic composition with increasing eutrophication, indicating total yield (as fish caught) of representative taxonomic groups from various North American lakes.

size-efficiency hypothesis of Brooks and Dodson (1965)), causing an overall reduction in herbivore size. Smaller herbivores cannot exert enough grazing pressure to control blooms of cyanobacteria and other noxious algae, which proliferate in eutrophic lakes and lower rivers in the absence of the large-bodied zooplankton. Turbidity can increase from higher cyprinid feeding activities and from loss of the littoral-zone filtering effect of macrophytes, further impairing visual predation by remaining piscivorous fish. Photosynthetic activity from the high algal biomass can elevate the pH to levels that adversely affect gill function in sensitive fish species.

Similar impacts on fish populations from loss of desirable littoral zone species have been documented in estuarine and coastal waters. For example, along the Swedish coast of the Baltic Sea, excessive nutrient enrichment has been related to increases in nuisance cyanobacteria and other filamentous species and a decrease in formerly dominant *Fucus vesiculosus* (Phaeophyceae), probably because of reduced light availability (Kautsky *et al.*, 1991, and references therein). This seaweed had provided critical habitat for herring spawns, and the shift to dominance by filamentous macroalgae led to decreased egg hatch in the herring populations.

Although aquatic birds and other vertebrates can move among aquatic environments with relative independence, some general effects of eutrophication on these macrofauna also have been described. Increased macrophyte vegetation under moderate nutrient enrichment in mesotrophic systems has been linked to increased numbers of herbivorous waterfowl such as moorhen (*Gallinula chloropus*) and whooper swan (*Cygnus cygnus*). Some piscivorous birds such as grebes and herons have also increased. As eutrophication progresses, however, bird species may decline following undesirable changes in food and habitat. For example, pochards (diving ducks, *Aythya ferina*) decreased on Lake Constance as their main food supply, the macroalga *Chara*, declined under nutrient enrichment. General macrophyte habitat loss under

nutrient over-enrichment has also been linked to the gradual disappearance of many waterfowl such as black and mute swans (*Cygnus atratus*, *Cited olor strepera*), Canada geese (*Branta canadensis*), coots (*Fulica atra*), teal (*Anas crecca*) and gadwells (*Anas strepera*). Sensitive life history stages of amphibians (e.g., frog eggs) have been killed in increasing hypoxic events within littoral zones of eutrophic lakes.

It should be noted that waterfowl and other wildlife can also act as eutrophying agents, especially in small lakes and coastal lagoons or poorly flushed embayments. Where waterbirds are abundant, exemplified by the increasing problem created by exotic (nonindigenous) Canada geese (*Branta canadensis*) in small ponds and other waters within urbanizing and agricultural areas of the US, their excreta can be a major nutrient source. For example, a small lake draining agricultural lands in the upper Midwest was used by Canada geese and other waterfowl (mostly mallards, *Anas platyrhynchos*, another exotic species). An analysis by Manny *et al.* (1994) estimated that the lake received ~70% of all external carbon sources, 27% of all N, and 70% of all P from the waterbirds. Overall, however, based on review of available studies, Hahn *et al.* (2008) reported that in most lakes, bird-mediated nutrient input is generally of minor importance compared with agricultural or sewage contributions.

Because of human disturbance, wildlife have also become important contributors of fecal bacteria and associated pollutants such as nutrients to some marine shoreline waters as a localized effect (Siewicki *et al.*, 2007). Coastal urbanization has increased impervious surface area, increasing runoff that is channeled into retention ponds or directly into waterways. These changes have increased the wildlife carrying capacity of the landscape, while also pushing wildlife (deer, raccoons, waterfowl, shorebirds) away from developed areas and into marsh edges near shellfish beds.

Aquatic Fauna and Inorganic Nitrogen Toxicity

Humans have dramatically altered the Earth's nitrogen cycle (Smil, 2001), and high levels of inorganic N enrichment to surface waters from fertilizer application and runoff, air pollution, human and animal wastes and other sources have been shown to impair the growth, reproduction, and survival of aquatic animals. Aquatic fauna can directly take up unionized ammonia (NH_3), NH_4^+ , nitrite (NO_2^-), nitrous acid (HNO_2), and NO_3^- from the surrounding water. Of these, following the excellent review of Camargo and Alonso (2006), NH_3 is the most toxic and NH_4^+ and NO_3^- are the least toxic, but even NO_3^- has a wide range of toxic effects at much lower concentrations that are commonly added to waterways by agriculture and other practices. As a generalization, estuarine and marine fauna appear to be comparatively more tolerant of the toxic effects of inorganic nitrogenous compounds than freshwater fauna, likely because of ameliorating effects of chloride and other ions.

NH_3 is highly toxic especially to fish and is thought to act through one or more of the following mechanisms: damage to gill epithelium, causing asphyxiation; stimulation of glycolysis, and suppression of the Krebs cycle, resulting in acidosis and reduced capability of the blood to carry oxygen; uncoupling of

oxidative phosphorylation, inhibiting ATP production and depleting ATP in the basilar region of the brain; disrupting blood vessels and osmoregulation, impairing liver and kidney functions; and suppressing the immune system, increasing susceptibility to disease. NH_4^+ ions can exacerbate NH_3 toxicity by reducing internal sodium ion concentrations. Environmental conditions such as increased pH, warmer temperatures, and low DO can increase fish susceptibility to NH_3 toxicity, and mixtures of NH_3 with other chemical pollutants such as certain heavy metals can result in additive or synergistic toxic effects. Freshwater invertebrates such as molluscs and planarians, and salmonid fishes appear to be most sensitive to NH_3 toxicity, and have sustained adverse impacts from chronic exposures to as little as $50 \mu\text{g NH}_3 \text{ N l}^{-1}$. Water quality recommendations developed in the US and Canada to protect sensitive aquatic life have ranged from $50\text{--}350 \mu\text{g NH}_3 \text{ N l}^{-1}$ for acute (short-term) exposures and $10\text{--}20 \mu\text{g NH}_3 \text{ N l}^{-1}$ for chronic (long-term) exposures. Such levels starkly contrast with concentrations commonly discharged in effluent from secondary sewage treatment across the US ($10^3\text{--}10^4 \mu\text{g NH}_3 \text{ N l}^{-1}$), animal waste spills ($10^4 \mu\text{g NH}_3 \text{ N l}^{-1}$), etc.

NO_2^- also inhibits nitrifying bacteria, which can result in its increased accumulation and intensified toxic effects. The main mode of action, especially in fish and crayfish, is conversion of oxygen-carrying hemoglobin or hemocyanin pigments into methemoglobin or methemocyanin forms that can no longer carry oxygen, leading to hypoxia and death. Other effects of NO_2^- toxicity in fish and crayfish have included depletion of chloride levels, leading to severe electrolyte imbalance; potassium ion imbalances that adversely affect membrane potentials, neurotransmission, skeletal muscle contractions, and heart function; formation of mutagenic and carcinogenic N-nitroso compounds; damage to mitochondria in liver cells, resulting in oxygen shortage; and immune system suppression. Elevated concentrations of certain ions such as chloride in brackish and marine waters are protective because they inhibit NO_2^- uptake. The most sensitive aquatic invertebrates tested so far have included decapod and amphipod crustaceans, ephemeropteran insects, and salmonid and cyprinid fishes. Based on acute toxicity data, it has been recommended that NO_2^- N concentrations should be maintained below $80\text{--}350 \mu\text{g l}^{-1}$ (depending on the organisms of concern) to protect sensitive aquatic fauna during short-term exposures.

The main mode of action of NO_3^- on aquatic animals is similar to that of NO_2^- . In experiments with aquatic organisms such as fish, reptiles, and amphibians, NO_3^- has also been shown to decrease immune response; to induce hematological and biochemical changes; and to adversely affect many metabolic processes by acting as an endocrine disruptor (Guillette and Edwards, 2005; Camargo and Alonso, 2006; McGurk *et al.*, 2006). Because fish and crayfish have lower branchial permeability to NO_3^- ions than to NO_2^- ions, uptake is more limited. The aquatic animals tested as most sensitive to NO_3^- toxicity are freshwater caddisflies, amphipods, certain amphibians, and salmonid fishes. For example, chronic NO_3^- toxicity for freshwater invertebrates can occur at values as low as $230 \mu\text{g NO}_3^- \text{ N l}^{-1}$ (0.23 mg l^{-1}). Lowest chronic toxicity levels reported for adult freshwater invertebrates were $2.8\text{--}4.4 \text{ mg l}^{-1}$ for two amphipod species; early instar caddisfly larvae sustained adverse effects from chronic toxicity at

1.4–2.4 mg l⁻¹. A threshold concentration of 1.1 mg NO₃⁻ N l⁻¹ significantly increased egg mortality of salmonids, and 1.6 mg l⁻¹ caused delayed hatching and development, and reduced weight in larval lake trout.

NO₃⁻ toxicity to aquatic life, historically, was dismissed as irrelevant, but that view has changed in consideration of the excessive NO₃⁻ concentrations that are now routinely added to surface waters and subsurface groundwaters by human activities (Stanley and Maxted, 2008, and references therein). Recent work suggests, for example, that excessive concentrations in agricultural areas such as the Corn Belt of the upper mid-western US (concentrations up to 25 mg NO₃⁻ l⁻¹ in receiving surface waters, and commonly above 5 mg l⁻¹ during crop fertilizer periods; Stanley and Maxted, 2008) are contributing to amphibian declines due to impaired swimming ability, decreased body size, and reduced fecundity and survival.

Oligotrophication – Reversing the Impacts of Eutrophication?

It is possible to reverse nutrient loading impacts in some aquatic ecosystems, at least partially, by reducing the nutrient inputs. This process can occur naturally when, for example, a major storm such as a hurricane causes high flooding or sedimentation that effectively reroutes a nutrient-rich tributary away from a receiving lake or estuary (such as an oxbow lake that is cut off from the main river); when natural flooding destroys a dam and eliminates a run-of-river impoundment; or when a raised bog system becomes isolated from nutrient-rich stream and groundwater sources. As nutrient loading declines, species diversity generally increases while the system production decreases. In ombrotrophic bog systems, there is also a shift over time to more acid-tolerant species, as the system's sole source of new water is low-pH precipitation.

Human influences are generally more pervasive than the natural forces that can contribute to oligotrophication. "Cultural eutrophication" is an acceleration of a long-term, natural process. Resilience, defined as the rate of recovery to the pre-disturbance state, depends on the initial status of the system in the natural eutrophication process, and on the degree of nutrient loading sustained. Ecosystem resilience is generally considered to increase with increased nutrient loading rate, and to decrease with increasing food chain length. Analysis by Cottingham and Carpenter (1994) suggested a modification of this relationship for pelagic food webs of north temperate lakes. In that analysis, planktivore-dominated (short-length) food webs were more resilient at baseline P loading rates of 0.1–1.0 µg l⁻¹ day⁻¹. Piscivore-dominated (long-length) food webs were more resilient at high baseline P loading rates (2.0 µg l⁻¹ day⁻¹), apparently because the additional nutrients were incorporated into the biota more rapidly due to their different growth requirements.

Eutrophic systems, dominated by generalist or opportunist species that are insensitive to the adverse impacts from nutrient over-enrichment, are considered to be relatively resistant to further change or stress as mentioned. Moreover, the adverse impacts of cultural eutrophication in such systems can be partially reversed in a relatively shorter period of time (several years). Less nutrient enriched systems (e.g., in early

phases of moderate nutrient enrichment or mesotrophy) have more specialized species, more opportunity for biotic adjustment of elemental cycles, and tighter coupling among element cycles. The diverse communities of such systems, comprised of more sensitive species, are relatively sensitive to further stress imposed by nutrient enrichment under accelerated eutrophication; and reversal or recovery to a pristine oligotrophic state is difficult to accomplish.

The degree of restoration success also depends on certain physical features of the system, especially mean depth and flushing rate. Aquatic ecosystems tend to retain most nutrients from loading events in the bottom sediments. PO₄⁻³ is especially "sticky"; it readily adsorbs to the iron oxyhydroxides of sediments, and to clays and other sediment particles. In deep lakes, most of the nutrient inputs from the previous years are unavailable to phytoplankton of the next growing season because the lower water column remains permanently stratified and, thus, isolated from the upper water column where the majority of the viable phytoplankton occur. In shallow systems, wind and internal currents mix the water column and surficial sediments completely, sometimes frequently over an annual cycle, so that some portion of the nutrients from the relatively rich bottom waters and sediments repeatedly becomes available for phytoplankton growth. Reservoirs, rivers, well-flushed estuaries, and wave-swept, marine coastal waters are usually less sensitive to nutrient loading and more easily "reversed" in the eutrophication process than lakes or poorly flushed coastal lagoons with long water exchange times (on the order of months to years), because the latter systems cannot flush the nutrient-laden water through and self-cleanse.

As other more practical considerations, the extent to which the acceleration of the eutrophication process can be reversed would be expected to depend on the feature of the aquatic ecosystem that is targeted for improvement. Nutrient reductions would exert the most direct effects on plant communities such as freshwater/estuarine phytoplankton or estuarine/coastal macroalgae. Thus, a goal of reduced incidence of algal blooms may be more rapidly achieved than the goal of improved fish communities, because fish growth is indirectly (mediated by changes in habitat) as well as directly (mediated by the food web) affected by the nutrient inputs. The economic feasibility of controls that can be exerted on anthropogenic nutrient sources is also important. Pragmatically, the highest prognosis for success would be expected for natural waters that are affected mostly by sewage and other point (pipe) source nutrient dischargers, because they are much easier to control than nonpoint (diffuse) sources.

One of the most famous early reports of successful reversal of cultural eutrophication involved removing sewage discharges from Lake Washington within metropolitan Seattle, WA, USA (Edmondson, 1970). This large, deep lake (128 km², maximum depth 59 m, mean depth 18 m) historically had shown water quality degradation in response to sewage inputs. In 1922, a diversion was created to carry the raw sewage from 30 outfalls away from the lake (into nearby Puget Sound). Algal blooms and fish kills soon abated. However, in 1930, sewage effluents began to be discharged into the lake from treatment plants in outlying communities, and noxious cyanobacteria blooms and hypoxia again increased. About 76 million liters of sewage without inorganic nutrient removal

were discharged daily into the lake by 1962. Nearly a decade of effort by a courageous limnologist, Dr T. Edmondson, led the city to support zero discharge of sewage into the lake by 1968 (Hampton *et al.*, 2006). By 1970, the phytoplankton growth had decreased to levels that had not been seen since the early 1950s, and the improvements in water quality and aesthetics were heralded by the citizenry as a rapid and remarkable recovery. This recovery was aided by the fact that the lake is relatively deep, and in addition the major nutrient sources to be controlled were sewage pipes. It is unlikely that the degree of recovery reversed the water quality and aquatic communities to a *ca.* 1930, more pristine status. However, the partial recovery (partial oligotrophication) represented a major improvement.

Other partial reversals of cultural eutrophication have been reported worldwide. In freshwaters they have been mostly achieved by targeting P reductions (but see below); in estuaries, both P and N have been reduced or “co-managed” for best results. Studies in north temperate estuaries by Fisher *et al.* (1992) and Chesterikoff *et al.* (1992) indicate that if only P – but not N – is removed from sewage inputs to upstream freshwaters, the P removal can actually exacerbate N-related eutrophication problems in downstream estuaries. The freshwater P reductions decrease the riverine algal growth that, if present, would also have removed a substantial portion of the N_i in the sewage before it reached the estuary. Soluble NO_3^- , in particular, is transported downstream at higher concentrations than if freshwater algal blooms had been available to consume it, and increased N_i is thus available to stimulate higher phytoplankton growth in the receiving estuary.

There is increasing recognition of the need to co-manage N and P in freshwaters as well as estuaries and marine coastal systems (Glibert *et al.*, 2011, and references therein).

As Glibert *et al.* (2011, p.359) wrote:

“A common practice has been to reduce P in point sources without concomitant reductions in N while overlooking the fact that nutrient loading results in large sediment deposits of nutrients that influence the overall system for an extended period (years) after loading rates are reduced. Reductions in anthropogenic P loads can initially result in a decline in phytoplankton biomass, but the sediment “pump” of stored P replenishes P supplies in the water column, promoting benthic productivity, which, in turn, has multiple effects on the food web. If the system additionally receives N, especially in the form of ammonium (NH_4^+), it can be expected to shift to undesirable dominant species among primary producers, with ramifications extending to higher trophic levels.”

P removal without N removal can also lead to major alterations in food web dynamics compared to systems where both N and P are removed, as organisms that are more efficient at sequestering P are favored. When one nutrient is altered relative to another, the stoichiometric balance in the water column is altered, and this change in turn moves through the food web. While less chlorophyll *a* may be supported in the water column, and waters may become clearer, increased non-native SAV growth (particularly invasive species such as *Hydrilla* and *Egeria*) can occur, leading to altered sediment nutrient chemistry, shifts in the dominant grazers, fish, and other changes. Partial reversals can achieve highly desirable results for resource managers and the general public, even if the recovered community is not the same as it was prior to eutrophication.

Importantly, however, there can be unintended as well as intended consequences from attempts to partially reverse eutrophication. For example, what is desirable for one constituency may not be for another: clearer water may be more desirable to the general public than floating algal scums, but decreased abundance of certain fish species, altered fish or shellfish community composition that coincide with the decrease in algae and the “clearing” effect may be undesirable for fishermen.

An example of partial reversal in eutrophication that achieved desirable effects for both the general public and fishermen is the case of Lake Erie in the 1960s–1970s (Ashworth, 1986). The degradation of fish communities in Lake Erie reached its most extreme level in the 1960s from a combination of eutrophication, overexploitation of fishery resources, extensive habitat modification, and other pollution. Beginning in the 1970s, fishery management strategies and pollution abatement programs contributed to a dramatic reversal. Lake Erie walleye fisheries rebounded to world-class status, and point-source P loading significantly declined, especially after sewage treatment was improved at the major point source discharger to the west basin of the Lake (the Detroit metropolitan wastewater treatment plant), and after mandated use of detergents without PO_4^{3-} . The P reductions effected in a dramatic decrease in the abundance of nuisance phytoplankton species and of zooplankton biomass, as well as a decline in the abundance of pollution-tolerant oligochaetes and an overall shift in macro-invertebrates to more pollution-intolerant taxa (but see below). Similarly, in the Bay of Quinte on Lake Ontario, P loading reductions after 1977 led to a decline in the abundance and biomass of oligochaete worms, sphaeriid molluscs, isopod crustacea, and some chironomids. Dominance in both chironomid and oligochaete communities changed toward species less tolerant of eutrophic conditions.

Nutrient reductions have led to success stories in estuaries and coastal lagoons. For example, industrial point source nutrient reductions to the Seto Inland Sea in Japan during the 1980s led to a noticeable decline in the frequency and magnitude of toxic dinoflagellate blooms (Okaichi, 1997). Nutrient loadings to Cockburn Sound, Australia, from industrial point sources, and reduction in nutrient loadings to Chesapeake Bay from sewage point sources have decreased phytoplankton blooms and promoted an increase in seagrass meadow habitat in some reaches of this estuary (Burkholder *et al.*, 2007, and references therein). Sewage discharges to the shallow estuary, Mumford Cove, in Connecticut, USA, were rerouted to another waterway in the late 1980s, and within two years massive nuisance blooms of the macroalga, *Ulva lactuca*, were eliminated (Harlin, 1993). The lagoonal New River Estuary, North Carolina, was one of the most eutrophic estuaries in the southeastern US during the 1980s–1990s. Because of high nutrient loads from a major military base and industrialized animal production, the estuary was characterized by dense harmful algal blooms, bottom-water anoxia and hypoxia, and fish kills. Upgrades in wastewater treatment systems during the late 1990s led to 57% and 71% reductions in N and P, respectively, to the estuary from point sources. Mallin *et al.* (1993, 2005) described the clear improvements as a result: major winter blooms of the harmful dinoflagellate *Prorocentrum minimum* disappeared, phytoplankton biomass

(as chlorophyll *a*) significantly decreased, inorganic N and P significantly decreased, and bottom-water DO and water clarity significantly increased, thereby improving habitat for the growth of sessile shellfish and seagrasses. Thus, partial “oligotrophication” from removal of sewage can have fairly rapid, positive results even in shallow systems where the sediments could provide some degree of nutrient replenishment to the overlying water.

Standing in marked contrast to these successes, however, are other situations such as the sobering recent developments regarding the noxious green macroalga, *Cladophora* in the Laurentian Great Lakes (see Burkholder 2009, and references therein). In the 1960s, benthic *Cladophora glomerata* (likely mixed with other *Cladophora* species) focused international attention especially on the west basin of Great Lake Erie, where it proliferated especially in response to P pollution from sewage and agricultural wastes. Its growth in relatively shallow nearshore waters appeared to be limited only by its relatively high light optimum for photosynthesis. Even so, its major seasonal die-offs that drifted into shore in rotting masses sometimes were measured in tons of fresh weight. The adverse effects of *Cladophora* overgrowth in Lakes Erie, Ontario, Michigan, and Huron included displacement of beneficial benthic plants, reductions in invertebrate densities and fish spawning, reduction in biodiversity, anoxia from decaying mats that results in killing of other aquatic life, retention of pathogenic microbes such as *Escherichia coli* and enterococci fecal bacteria as a potential human health hazard, negative effects on recreational use of affected shorelines and nearshore areas, and depressed property values of adjacent homes. Concerted multibillion dollar efforts that banned P use in detergents and improved P removal in sewage treatment during the 1970s led to a dramatic decrease in *Cladophora* in the Great Lakes by the early 1980s.

The success was painfully short-lived. Dissolved PO_4^{3-} concentrations again increased in nearshore lake waters since the late 1980s from altered sediment P fluxes (that is, increased P coming up from the sediments) due to altered benthic biogeochemistry and feces and other metabolic wastes of massive invasions of exotic zebra mussels (*Dreissena polymorpha*) and quagga mussels (*Dreissena bugensis*), which now dominate the nearshore benthic environment along with *Cladophora*. In fact, the macroalgal biomass is again similar to the situation sustained by the Great Lakes during the 1960s–1970s. Through their filtering activity, the huge populations of exotic invasive mussels also increase water clarity during the spring growing season for *Cladophora*, while their excreta, together with the high algal productivity/decomposition, alter sediment P fluxes and fertilize the benthic and shallow-water nearshore habitats. Importantly, removal of P from external loads tends to accelerate the dynamics of P recycling from the benthos into the water column, and can result in a “cascade” of ecosystem changes. *Cladophora* growth now covers a broader range of depths, an expansion that has been attributed to the increased available light and within-lake P supplies. Thus, and ironically, within-lake P loads contributed by the exotic invaders and the altered sediment P fluxes are now even more important than external P loads in sustaining massive *Cladophora* blooms that have returned to the Great Lakes.

In a recent review, Duarte *et al.* (2008) assessed the recovery of a group of ecosystems after nutrient removal, found that the trajectories of response are variable and complex, and attributed this

variation to “shifting baselines” caused by other changes such as exotic species invasions, extinctions, overfishing, and climate change. It was concluded that because of these additional changes, reductions in nutrient loads alone cannot be expected to allow systems to return to conditions that existed decades earlier. Reductions in P or N have reduced total phytoplankton biomass in many systems, but such shifts to an alternate stable state do not necessarily return the system to its pre-eutrophic state because the system may be more susceptible to other stressors such as exotic species invasions. Reduction of one nutrient but not the other, changes the N : P ratio which, in turn, alters metabolism, species composition across trophic levels, and food webs (Glibert *et al.*, 2011, and references therein). Thus, from an overall ecosystem standpoint, the extent to which aquatic habitats can be “reversed” in the cultural eutrophication process depends on a more complex “endpoint” than variables such as reductions in nuisance algal growth, recovery of beneficial macrophyte beds, or increases in desirable fish species. The full range of chronic impacts from variables that frequently accompany nutrient enrichment remain to be resolved before the full extent of impacts from cultural eutrophication on aquatic ecosystems, and the potential degree of reversing those impacts, can be evaluated.

Glossary

Adaptation Increase in fitness due to response to natural selection.

Gene flow Dispersal of individuals (or pollen) between populations, resulting in a genetic contribution from one population to another.

Genetic drift Random change in the frequency of alleles or genotypes within a population.

Genetic variation Variation in traits attributable to genetic differences among individuals in a population.

Habitat fragmentation Subdivision of wild habitat, coupled with conversion of wild habitat for use by humans (e.g., agriculture, urbanization).

Heritability Genetic variation expressed as a proportion of the overall variance in a trait.

Inbreeding Mating between relatives. This results in progeny that carry two copies of the same allele at many loci throughout the genome.

Mutation A heritable change in the nucleotide sequence of an organism.

Natural selection Variation among individuals in their contribution of offspring to the next generation. To the extent that this variation in offspring number is associated with genetic differences among individuals in the population, natural selection results in change in the population's genetic composition and tends to increase its average fitness.

Phenotypic plasticity Response of traits to the environment in which an organism develops.

Provenance test An experiment, particularly in forestry, in which plants from different source locations are grown together in common conditions (also referred to as common gardens), often in multiple locations, as a basis for assessing genetically based differences in trait values.

Introduction

Research on evolutionary responses of wild populations to climate change has been stimulated by accumulating evidence demonstrating exceptional rapidity of recent climate change and predictions of rapid change in climate into the future. However, it is challenging to demonstrate empirically that observed changes in wild organisms are due to changing climate *per se* because of the complex dynamics of both climate and evolution.

Climate is Complex

Climate comprises many attributes (i.e., temperature maxima and minima, rainfall, humidity, insolation, all varying over the seasons) and is manifest over extended periods, rather than instantaneously. Consequently, climate cannot be imposed or manipulated experimentally, though individual components of it can be, on a limited spatial scale. In nature, climatic variation is correlated with other aspects of the environment; for example, temperature regimes vary latitudinally along with photoperiod; characteristics of soils vary, in part due to the effects of water percolating through them (Baldwin *et al.*, 1938). Moreover, erratic variability in climate is superimposed on the regularity of annual climate cycles; forecasts indicate that climate variability will increase, such that extremes occur more frequently (Alley *et al.*, 2007).

Evolution is Complex

The complexity of climate is matched by that of evolution, defined as genetic change in populations over generations. Genetic change results from any or all of four evolutionary processes: natural selection, genetic drift, mutation, and gene flow between populations that have diverged genetically (Hartl and Clark, 2006). However, some changes that are observed as environment changes, for example, in flowering time, or migration date, may reflect direct effects of environment on individuals during their development, i.e., phenotypic plasticity (Bradshaw, 1965). Thus, conclusive assessment or prediction of evolutionary change entails multigenerational studies designed to distinguish genetic from environmental responses. Evolutionary theory, developed over nearly a century, ameliorates these challenges by grounding and guiding evolutionary explanation and prediction.

Populations Have Evolved in Response to Climate Change in the Past

Despite the inherent complexities of both climate and evolution, which impose formidable challenges to study of evolutionary responses to climate change, it is well established that populations have adapted to different climates in the past. Climate has resulted in evolutionary convergence of morphological and physiological traits in unrelated taxa as illustrated by the increase in wind pollination during the arid Eocene period (Crepet, 1989) and rise of C4 photosynthesis during a period of low CO₂ concentration during the Miocene

(Ehleringer *et al.*, 1991). It is clear that on a geological time scale, natural selection due to climate has powerfully shaped the attributes of organisms.

Populations Will Evolve in Response to Climate Change in the Future

As climate continues to change, natural selection is expected to change such that different trait values will be favored, compared to the past or present. For example, natural selection may favor traits associated with earlier phenology or enhanced tolerance of drought or heat. If populations harbor genetic variation for traits under selection (and other genetic and demographic aspects of the population are conducive to evolutionary change, *see* Evolutionary Rates), populations are expected to adapt in response. Beyond altering natural selection, changes in climate are also likely to influence other evolutionary processes such as gene flow, genetic drift, and inbreeding.

What is this Article About?

Here the authors review basic concepts in evolutionary genetics with an emphasis on how they pertain to studies of the adaptation to climate change. They focus on evolutionary responses of wild populations inherently subject to the fundamental evolutionary processes; they do not consider domesticated populations, in which genetic change is dominated by decisions of breeders. The authors provide an overview of approaches that have been employed to elucidate adaptive evolution in natural populations in response to both geographical variation in climate in the past and to contemporary climate change. These approaches include observational studies conducted across spatial and temporal gradients, experimental manipulation of genetic and environmental factors, prediction of future evolution based on standing levels of genetic variation and selection gradients, and simulation modeling of evolutionary change.

Overview of Evolutionary Genetics

Populations are constantly changing. An increasing number of studies have documented changes in natural populations, even over a few generations (Grant and Grant, 1993; Reznick *et al.*, 1995; Bradshaw and Holzapfel, 2001; Réale *et al.*, 2003; Franks *et al.*, 2007). However, it is important to recognize that not all changes that have been observed in recent decades (e.g., Walther *et al.*, 2002) in natural populations reflect evolutionary responses to natural selection. A clear distinction needs to be made between “environmental response” and “evolutionary response.”

Environmental versus Evolutionary Response

Environmental response of organismal traits, or phenotypic plasticity, reflects the direct dependence of organisms’ physiology, growth, development, and behavior on the environmental conditions they experience through their lifetimes (Bradshaw, 1965). Plastic responses do not involve changes in

the genetic composition of a population but manifest environmental influences on the expression of genes (e.g., flowering time, Aikawa *et al.*, 2010). In contrast, evolutionary change is the change over generations in the genetic composition of a population. All populations are continually subject to evolutionary change. It results from several processes, including natural selection, i.e., variation among genotypes in survival or reproductive success. Natural selection is the basis for adaptation. Genotypes that express adaptive phenotypes make a greater genetic contribution to the subsequent generation; in this way, alleles that confer higher fitness in a given generation gain in frequency in the population. Natural selection may also favor plasticity that maintains high fitness in a variable environment. For example, a genotype that produces thin leaves in mesic conditions but thicker leaves when it develops in more arid conditions may have a survival or reproductive advantage over genotypes that do not respond in this way. If there is variation among genotypes in their phenotypic plasticity and this variation is under selection, plasticity itself can evolve (Via, 1993).

In the context of climate change, phenotypic changes such as timing of flowering and breeding that correspond statistically with recent climatic trends are well documented (Parmesan and Yohe, 2003). Observation of such changes does not reveal the basis of these responses, whether plasticity in response to immediate environmental condition, adaptive evolution in response to selection mediated by environmental change, or a combination of these. Phenotypic plasticity may buffer populations against natural selection in the short term. However, the limits of phenotypic plasticity in maintaining fitness over a range of environments are poorly understood, and, over the long term, ongoing climate change is expected to exceed those limits (DeWitt *et al.*, 1998). Thus, as climate continues to change, it is likely that natural selection will alter plasticity of traits as well as their expression in particular environments, given climate model predictions that include both directional change and increased variability.

What is Natural Selection?

Natural selection occurs when genotypes in a population differ in fitness, their contribution of progeny, and the genes they carry, to subsequent generations. Over generations, natural selection is expected to increase the average fitness of populations in the environments in which they undergo selection. This process of adaptive evolution proceeds over generations at a rate that depends on the severity of genetic selection, the genotypic variation in fitness.

Climate conditions that are novel relative to previous ones at a particular location are likely to impose a typically strong directional selection on traits, such as rooting depth, that are related to survival in dry conditions. This would be expected even if climatic changes were smooth. However, the prediction that climate is becoming more erratic implies that bouts of intense selection in one direction (e.g., favoring greater drought tolerance) will be interspersed with weaker selection or even selection in the opposite direction. Evolutionary dynamics may be governed by such extreme selective events (Grant and Grant, 2002; Gutschick and BassiriRad, 2003).

Evolutionary Rates

The rate of evolutionary response to selection depends on both genetic variation and environmental conditions and is most simply illustrated by the *breeder's equation* (1). The expected amount of phenotypic change (R) in a single trait per generation in response to selection depends on the strength of selection on that trait as measured by the selection differential (S), a statistical measure of the association between fitness and trait values, and also on genetic variation for the trait as expressed by heritability (h^2):

$$R = h^2 S \quad [1]$$

Heritability (h^2) estimates the fraction of the total phenotypic variance (V_P) due to additive genetic variance (V_A):

$$h^2 = V_A / V_P \quad [2]$$

V_A is the variance in a trait that is attributable to segregation of alleles at all the genes that influence that trait, and the resemblance of relatives due to sharing of alleles at all these genes is proportional to h^2 (Falconer and MacKay, 1996). V_A , V_P , and S are not static quantities. The expression of additive genetic variance and the total phenotypic variance depend on the immediate environmental conditions, as does the selection differential. Thus, estimates of heritability and selection are context dependent and are applicable to prediction of selection only in the specific environment for which they have been estimated.

The single-trait breeder's equation is not adequate to describe response to selection when multiple traits are under selection and are genetically correlated with each other. Genetic covariance between pairs of traits, each subject to selection, can promote the response of each to selection, if, for example, the sign of the genetic covariance is positive and both traits are selected in the same direction. Conversely, a positive genetic covariance between traits impedes response of both traits to selection if higher values of one trait and lower values of the other are associated with higher fitness. The genetic variances of traits and the genetic covariances between pairs of traits depend on direct effects of environment on organisms and the traits they express; genetic variation in traits and fitness may be reduced (Hoffmann and Parsons, 1991) or enhanced (e.g., Shaw *et al.*, 1995) in harsh environmental conditions.

Genetic correlations between traits can be included in predictions of selection response using a multivariate extension of the breeder's equation:

$$\Delta \bar{z} = G \beta \quad [3]$$

where the predicted change in the means of a set of traits (expressed in a vector, $\Delta \bar{z}$) across one generation depends on the additive genetic variance–covariance matrix (G) and the vector of selection gradients (β) (Lande, 1979). As in eqn [1], use of this expression to obtain predictions of selection response requires taking the product of two estimates, each of which has substantial statistical uncertainty due to sampling and measurement error. Thus, interpretation is not straightforward. Alternatively, the response to selection can be estimated directly as the additive genetic covariance between

relative fitness and traits (Price, 1970):

$$\Delta \bar{z} = \text{Cov}_A[w, z] \quad [4]$$

where w is individual relative fitness (absolute fitness divided by mean fitness), and z is the vector of trait values (Shaw and Shaw, 1994; Etterson and Shaw, 2001; Hadfield *et al.*, 2010).

What Processes Influence Genetic (co)variance?

As with additive genetic variances, additive genetic covariances also depend on a population's genetic composition, and strong selection over the extended period of climate change may radically deplete genetic variation. Spontaneous mutation steadily augments genetic variation; under changing conditions, novel mutations may more likely contribute to ongoing adaptation. Furthermore, influx of genes from genetically divergent populations increases genetic variation. Consequently, G (eqn [3]), which governs the immediate response to selection, i.e., from the current generation to the next, is expected to change with ongoing climate change, though the net effect of all the processes that influence G is not readily predictable.

In populations where climatic conditions become so severe that population size drops dramatically, genetic variation is expected to decline due to genetic drift. By this process of random sampling, genes that could contribute to adaptation can be lost (e.g., Weber and Diggins, 1990). Moreover, as populations decline in size, inbreeding increases, reducing fitness itself (i.e., inbreeding depression) further impairing populations' capacity for increase. Inbreeding may also slow the response to selection (e.g., Shaw *et al.*, 1998). Moreover, the number of new mutations in a population declines directly with the population's size, with the consequence that particular mutations, for example, those that could support adaptation to changing climate, are less likely to arise. These considerations underscore the intimate connection between the demography of populations and changes in their genetic composition. Evolutionary theory before 1990 tended to ignore this connection, but such simplification is especially likely to mislead in circumstances when conditions are so severe that populations become small and are at risk of extirpation. In many cases, such populations are likely to die out. For others, immigration can play the important demographic role of increasing the size of a population, enhancing its chance of persisting, in addition to contributing to its genetic variation (Holt and Gomulkiewicz, 1997).

Evolution of Plasticity

The tendency for natural selection to favor adaptive plastic responses will depend on the extent to which climate increases in variability. In the simplest case, if climates were to change monotonically (e.g., becoming progressively warmer or drier), then natural selection may favor adaptive evolution via fixed genetic changes that result, for example, in earlier breeding or greater thermal/drought tolerance. However, in the more realistic case in which climate variability increases (Alley *et al.*, 2007), and hence variability in natural selection does also, then adaptation involving plasticity may enhance fitness

across a range of environments. However, reversals in genotypic fitness, either within the lifetime of an organism or between generations, are expected to impede evolutionary increase in population mean fitness because genotypes with high fitness under both sets of conditions will be rare (Via and Lande, 1985; Gillespie and Turelli, 1989; Van Tienderen, 1991; Gomulkiewicz and Kirkpatrick, 1992; Gavrilets and Scheiner, 1993a, b). Adaptive plasticity is also less likely to evolve in a highly erratic and unpredictable climate marked by extreme events.

Approaches to Understanding Evolution in Response to Climate Change

Adaptation to Climate in the Past

Past evolution in response to climate is evidenced by the current adaptation of organisms to their home environments, encompassing climate, among many other aspects. A high degree of adaptation to an environment is reflected in high fitness (comprising individual survival and reproduction) that contributes to persistence of a population in that environment. This implies that, in previous generations, the population has undergone natural selection in those (or similar) conditions and, as a consequence, its genetic composition has changed, with increased frequency of genes conferring greater fitness than would otherwise be the case.

Range Limits and Climate Variables

The limits of species' ranges commonly coincide with abrupt spatial gradients in climatic attributes, and the geographic extent of a species' range can sometimes be predicted with high confidence from climate data taken in a subset of its range (Peterson *et al.*, 1999). The geographic ranges of species have shifted during past periods of climate change and shifts in range are ongoing. Shifts of the range of species may be an important component of the biological response to climate change in the future. However, it is not clear that range shifts of populations will proceed at sufficient rates, such that they will be subject to similar climatic conditions as climate changes. For example, it is often suggested that severe fragmentation of contemporary habitat is likely to impede dispersal. Moreover, interactions within and between species may thwart establishment of a population in locations beyond the current range where climate has become suitable for it. Beyond the role of geographic shift in a species range, the evolution of range limits is expected, even in the absence of climate change (Kirkpatrick and Barton, 1997).

Geographic Variation among Populations within a Species

Species that occur across environmental gradients frequently express clinal patterns in phenotype that may suggest underlying local adaptation. However, these patterns do not necessarily reflect genetic differentiation, but may result from phenotypic plasticity, which may or may not be adaptive. The extent to which clinal patterns in phenotype can be attributed

to genetic differentiation, phenotypic plasticity, or some combination of these can be ascertained through "common garden" experiments in which populations are sampled from an environmental gradient and reared in common conditions (e.g., Reinartz, 1984; Lacey, 1988). By subjecting the populations to the same environment, such experiments demonstrate that differences detected among them in morphology, physiology, and phenology, in the common garden setting, must be genetically based. Furthermore, if this differentiation is related to the gradient from which they were sampled, they will retain clinal patterns in a common environment (e.g., Etterson, 2004a). Clinal patterns that disappear in a common garden can be attributed to phenotypic plasticity (e.g., Maherali *et al.*, 2002). Expanded forms of the common garden approach involve multiple growing locations, including reciprocal transplant studies (Clausen *et al.*, 1940; Etterson, 2004a, b) and provenance trials (e.g., Rehfeldt *et al.*, 1999). These experimental designs make possible comparisons of the relative adaptation of populations under different climatic conditions, and in relation to the climates at the locations from which the populations were drawn. Manipulation of some particular aspect of climate as an added experimental component of a common garden may yield yet stronger evidence of past adaptation to prevailing climatic conditions.

Observations Over Time

Evolutionary response to climate change has already been documented for a few wild organisms for which long-term studies of field populations have been conducted. For example, over the past 30 years mosquitoes that breed in pitcher plants in the eastern US have evolved different genetically based photoperiodic cues for breaking dormancy that correspond to increases in the length of the growing season in recent decades (Bradshaw and Holzapfel, 2006). In Australia, 20 years of temporal sampling of fruit fly populations has demonstrated latitudinal shifts of clinal variation of genetic traits (Umina *et al.*, 2005). Rapid evolution of clinal variation has also been observed for several invasive species since the time of establishment (e.g., Huey *et al.*, 2000). It has also been inferred that the timing of breeding has evolved in a population of red squirrels in Canada. In the last decade, spruce trees have been producing their cones progressively earlier (Réale *et al.*, 2003), and this has exerted selection on the squirrel population resulting in earlier breeding. By tracing the inheritance of timing of breeding from parents to offspring for several generations, these researchers undertook to distinguish genetic change from phenotypic plasticity and ultimately attributed the observed changes to both. The authors note, however, that Hadfield *et al.* (2010) have called the conclusions of this and some other studies into question because the statistical methods used do not fully account for sampling variance. Given the difficulty in obtaining high-quality empirical data sets of this kind that are sufficiently large to allow robust methods of analysis, it is not surprising that there are few unequivocal examples of genetically based evolution in response to contemporary climate change (Gienapp *et al.*, 2008).

Resurrection Ecology

In a few cases, direct demonstration of the nature of contemporary change in wild organisms has been possible because propagules (e.g., seeds in tundra soil or eggs in lake sediments) were recoverable or fortuitously available such that ancestors could be revived and compared side-by-side with their descendants (Bennington *et al.*, 1991; Vavrek *et al.*, 1991; Hairston *et al.*, 1999; Kerfoot *et al.*, 1999; Franks *et al.*, 2007). This “resurrection approach” (Davis *et al.*, 2005; Franks *et al.*, 2008) has permitted phenotypic and genetic comparisons of populations representing different times. The work of Franks *et al.* (2007) illustrates this approach. They compared the date of first flower of plants that were revived from seeds stored in 1997 with that of plants grown from the seed of their descendants sampled in 2004 following an intervening drought. This comparison yielded estimates of rates of evolution and comparison with changes predicted from quantitative genetics theory.

Experimental Manipulation of Population Genetics

Artificial selection involves experimental imposition of selection to answer questions about potential rates of evolutionary change. In practice, a researcher selects from a population individuals that express phenotypes of interest, for example, drought tolerance or earlier flowering. The selected individuals are interbred with the expectation that, if the trait is heritable, its phenotypic mean will differ in the offspring of the subsequent generation. From eqn [1] we can see that if the strength of selection (S) is experimentally determined and the response to selection (R) is observed, we can estimate the realized heritability (h^2) of the trait of interest. An alternative approach is to expose a population to an environment (e.g., higher temperatures) in which genetic variation in fitness is expressed, such that natural selection proceeds (Bennett *et al.*, 1992). Following several to many generations, fitness and other traits are compared between the selected and control populations to determine the extent of evolutionary change. Experimental evolution by either of these approaches may demonstrate evolutionary change in numerous traits.

Information obtained from studies of experimental evolution has improved our understanding of biotic response to climate change in numerous ways. For example, artificial selection studies have shown that it is possible that shifts in flowering time in herbaceous plant species that have been observed in nature (Parmesan and Yohe, 2003) may be due, in part, to evolutionary change (Burgess *et al.*, 2007). In bacteria, studies where organisms evolved under experimental conditions have resulted in dramatic adaptive evolution in thermal tolerance (Lenski, 2001). It is particularly notable that adaptation proceeded in populations that initially lacked genetic variation; thus the adaptation that occurred depended entirely on newly arising mutations, and proceeded even under conditions of fluctuating selection. Mongold *et al.* (1999) have further shown that genes that can support adaptation beyond the presumed lethal thermal limit of *E. coli* fail to increase in frequency in competitive conditions. Consequently, only when populations decline in abundance does

adaptation to such extreme thermal conditions proceed, a clear example of the intimate connection between demographic and genetic change. In contrast to the previous examples, some experiments to evaluate potential for adaptive evolution in response to aspects of global change have detected only limited evolutionary responses. Potvin and Toussaint (1996) manipulated both temperature and CO₂ concentration and found that responses of wild mustard following seven generations in those conditions were primarily through nonadaptive plasticity. In summary, experimental evolution is a powerful approach that will continue to elucidate the rate of evolutionary change, the presence of genetic variation for traits that are under selection, and the role of genetic correlations in evolutionary change.

Prediction of Future Evolutionary Trajectories

To predict adaptation in response to climate change, we need estimates for three fundamental pieces of information: the strength and direction of selection in future climates, the genetic variances of traits that are under selection in altered environments, and the extent to which these traits are genetically correlated with other traits.

Selection regimes currently impinging on populations at lower elevation or latitude may simply shift to higher elevations or latitudes as climate warms and the geographical ranges of species track these shifts. However, populations may change in more complex ways because the ecological context, both abiotic and biotic, will be altered. Paleocologists, having extensively studied assemblages of species in the past via the pollen record, have frequently noted that these assemblages often do not have present-day analogs, which suggests that environmental conditions are not closely replicated in different eras. A direct way to assess trends in selection is to do phenotypic selection analyses on data collected from long-term studies of field populations. However, data sets that are complete enough to document such temporal changes in selection on wild populations are rare (but see Grant and Grant, 1995). An alternative approach is to compare natural selection in current environments to selection in experimental conditions similar to those predicted for the future. However, most studies that have manipulated environmental conditions, such as temperature, precipitation, and CO₂ have focused on changes in species composition rather than on patterns of natural selection, although there are a few exceptions (Totland, 1999). Insight into temporal changes in selection may also be obtained by characterizing changes in selection along environmental gradients that encompass a range of conditions similar to those predicted for a given location in the future (i.e., a chronosequence, Etterson, 2004a). This approach may provide an incomplete picture of future selection because native species composition will also be altered by climate change and invasive species, pests, and diseases may invade new territories and alter patterns of selection. Furthermore, patterns of selection may be more erratic in the future if climates become more prone to extreme events such as drought, heavy precipitation, heat waves, and intense tropical cyclones (Alley *et al.*, 2007).

Theory for Evolutionary Response to Changing Environment

The persistence of populations in changing environments depends on both evolution and demography. Theory that couples evolutionary and demographic dynamics of closed populations has shown that even if adaptive responses are possible, densities may fall below some critical level such that populations are susceptible to extinction by stochastic processes (Bürger and Lynch, 1995; Gomulkiewicz and Holt, 1995). Genetic variation in a trait subject to changing selection as environment changes can enhance the persistence of populations in a changing environment whether the population shifts in its range in conjunction with the changing environment (Pease *et al.*, 1989) or not (Bürger and Lynch, 1995).

Levels of genetic variation and therefore, the potential for adaptive evolution, are not likely to be uniform among populations across the species range (Antonovics, 1976; Lenormand, 2002). As populations become increasingly fragmented, with reduced dispersal among subpopulations, their potential for local adaptation is expected to increase (Dickinson and Antonovics, 1973; Garcia-Ramos and Kirkpatrick, 1997). Nevertheless, even if marginal populations are not swamped by gene flow from central populations, adaptive evolution may be slowed due to strong selection causing genetic variance to be depleted (Fisher, 1930). Genetic drift may also erode genetic diversity, especially in small and isolated populations near the periphery of the species range or in remnant populations (Wright, 1931; Nei, 1973). Thus, fitness may be positively or negatively influenced by gene flow between populations. Adaptation may be more rapid with gene flow, both because it increases genetic variation in traits subject to selection (Swindell and Bouzat, 2006) and because it impedes genetic drift (Lopez *et al.*, 2009), even in an environment that is constant through time. In populations spanning gradual environmental gradients, gene flow between adjacent populations is not expected to inhibit local adaptation because populations are similarly adapted. Marginal populations evolve in response to extreme conditions expanding their tolerance limits and geographic ranges. However, if the environmental gradient is steep, the process of local adaptation is swamped by gene flow between populations that are adapted to substantially different environments (Kirkpatrick and Barton, 1997).

Summary

Evolution proceeds unceasingly in all biological populations. Rapid adaptation to human-mediated environmental change was evident long before climate warming became apparent. Consequently, there is no doubt that natural populations will continue to evolve and, in particular, that adaptation to changing climate is possible, in principle. However, it remains unclear how the several evolutionary processes – natural selection, mutation, gene flow, and genetic drift – will jointly alter any single population or the biota collectively. Even though natural selection is likely to proceed, there is insufficient understanding to predict for how many species and which species the rate and extent of adaptation will be

adequate to support persistence, given the very high rates of environmental change expected. Such predictions will require further empirical investigation (experimental, as well as observational) of genetic variation and natural selection, directly accounting for increasing variability of climate. Moreover, the remaining evolutionary processes and their interplay, all of which are sensitive to demographic aspects of populations, are expected to bear importantly on genetic change in nature. Research that accounts for these processes, as well as natural selection, will yield more reliable prediction of evolution and species persistence in the face of changing climate.

Glossary

Fire regime The type of fire, mean and variance in fire frequency, intensity, severity, season, and areal extent of a burn in an ecosystem.

Fire-stimulated recruitment Seedling recruitment in the first one or two growing seasons after a burn.

General circulation model (GCM) Computer models developed to simulate global climate and widely used for global climate change predictions.

Prescribed burning Fires intentionally lit for management purposes.

Serotiny Seeds stored on the plant with dispersal triggered by fire.

Fire in Earth History

Fire is an enormously influential disturbance over very large areas of land in the modern world. Vegetation burns because the earth's atmosphere contains sufficient oxygen (> 15%) to support combustion. Should oxygen levels rise above 30%, fires would be so frequent that dense forest vegetation, even in persistently wet climates, would be incinerated. There is an almost continuous record of fossil charcoal over the past 350 million years indicating that the atmosphere supported combustion for most of terrestrial plant evolution. Oxygen levels reached maxima in the Upper Carboniferous, 300 million years ago (Ma), when abundant fossil charcoal indicates frequent fires. Fires were also common during the Cretaceous (135–165 Ma) when flowering plants (angiosperms) first began to spread. Fossil flowers, with fine structure beautifully preserved as charcoal, are common and widespread in Cretaceous deposits. At these and other times, frequent fires may have played a significant part in the ecology and evolution of paleo-ecosystems (Bowman *et al.*, 2009).

Broadleaved forest, analogous to present-day tropical and temperate forests, first became globally widespread in the Eocene (55–35 Ma) a warm wet period. Fossil evidence for fire is rare at this time but dated molecular phylogenies indicate that fires were continuing to burn in Eocene landscapes. Grasslands are the most flammable vegetation that has existed in earth history. Tropical (C4) grasslands and savannas are the most extensive flammable biomes today occupying one-fifth of the world's land surface. Though C4 grasses are ancient (30 Ma), the savanna biome first began to spread from the late Miocene (8 Ma). Charcoal from marine sediments increased dramatically during the past 10 Ma as fire-promoting ecosystems, including savannas, began to spread.

Hominids have used lightning-ignited fire for perhaps as long as 1–1.5 My but first began to ignite their own fires from 200 to 400 ka. Fire was used as a tool for managing the environment to promote the growth of edible plants in hunter-gatherer communities and to attract animals to hunting grounds. Fire was (and is) a tool used by farmers to clear new lands and to prepare sites for swidden-type farming. However, the historical impact of human use of fire on the environment may be less than previously assumed.

Increases in charcoal in south-east Asia (50 ka) and Australia (60–45 ka) are coincident with the arrival of fire-using modern humans. However, charcoal records from Europe reveal that climate change, rather than changes in human use of fire, best correlates with fire activity from 70 to 10 ka (Daniau *et al.*, 2010). Charcoal records from around the world for the past two millennia indicate little impact of humans on biomass burning until as late as the mid 1700s with an abrupt decline in burning after 1870 (Marlon *et al.*, 2008). Thus, the area burnt by vegetation fires may be at its lowest level for the past few millennia.

World Biomes and Fire Incidence

Satellite imagery is beginning to reveal the vast global extent of fires. Between 1997 and 2008, the average global burnt area was 3.7 million km² or 2.8% of the total unglaciated land area (Giglio *et al.*, 2010). Nearly one-third of the land surface experienced fire activity between 2001 and 2006. Africa accounts for about 70% of annual burnt area with the remaining 30% primarily in Australia, followed by South America and Central Asia. Fires are rare only at the extremes of the climatic continuum. The most humid tropical and temperate forests and the driest deserts have the smallest proportion of burnt area annually. However, between these two extremes, fire has influenced the extent and composition of a great diversity of ecosystems, including tropical grasslands and savannas, temperate grasslands and steppe, boreal forests, dry conifer forests, temperate woodlands, Mediterranean-type shrublands, heathlands, and eucalypt woodlands. Forests with mast-flowering bamboo understories are also prone to burning after the bamboos flower and die, creating massive fuel loads. Humans have changed landscape patterns of burning. Even humid tropical forests are beginning to burn as a result of logging and deforestation fires. All these biomes experience fires of widely differing frequency and severity which help shape ecosystem structure and function.

Given its wide geographic extent, fire inevitably influences the distribution and abundance of many species. Some ecosystems are dominated by species that depend on fire to complete their life cycles. Others are dominated by species that tolerate burning but have no direct dependence on fire.

Ecosystems that seldom or never burn, except when disturbed by human activity, contain mixtures of species that fortuitously tolerate burning and species extremely intolerant of fire. The impact of burning on biodiversity varies greatly among these different types of ecosystems and species-response patterns.

Determinants of Fire

The incidence of natural fires depends on much the same combination of ingredients as a campfire: dry fuel, flammable material (finely branched plant material that dries quickly), continuity of fuels, and a source of ignition. Suitable weather conditions and winds to carry the fire and preheat flammable material are also the key factors. The flammability of vegetation varies with the moisture content of plant biomass. Dead matter has the lowest moisture content, whereas live leaves will burn more easily if their moisture content is low. The shape, size, and arrangement of plant parts influence moisture content and flammability. Plants with narrow leaves or thin branches dry rapidly and burn readily. Ecosystems that accumulate slow-decomposing litter are highly flammable. Leaves with large amounts of oils, fats, waxes, and terpenes also burn readily. Volatile substances enhance burning because they are released from leaves, burn fiercely, and thus dry and heat adjacent material.

Because fire depends very much on moisture content of vegetation, climate and weather conditions exert marked influences on the timing of burns. The length of a warm, dry period needed for ignition depends greatly on vegetation properties. A few days of hot, dry weather are sufficient to dry tall grasslands enough to sustain a fire, whereas months of extreme hot and dry conditions are needed for fire to burn pristine humid tropical forests. Therefore, large fires in woody ecosystems are generally associated with rare drought events, such as those produced by El Niño conditions. In contrast, large fires in arid grassy ecosystems are limited by the availability of fuel and are more common after high rainfall years. Fires generate their own heat that, under hot, dry, and windy conditions, creates a positive feedback, increasing the area burnt and the severity of the fire by drying the vegetation before the fire front.

A source of ignition is needed to start fires. Today, most fires are ignited by humans, except in sparsely populated regions. Lightning fires are still common in many landscapes. Lightning often accounts for large numbers of fires but small areas burnt because many are doused by subsequent rain or controlled by fire crews attuned to the risk of thunderstorm fires. Rockfalls also ignite fires, accounting for the spate of burns often triggered by earthquakes. Volcanic activity is of local significance, especially on islands in which lightning is unusual. The contingent requirements of ignition, suitable weather conditions, and contiguous flammable vegetation make for a high degree of uncertainty in predicting landscape fire patterns.

The Fire Regime

The ecological effects of fire depend on the fire regime rather than the occurrence of a single fire. The fire regime is produced

by the combined effects of climate, fuel properties of vegetation, and ignition frequency. It is characterized by the type of fire, mean and variance in fire frequency, intensity, severity, season, and areal extent of a burn. Types of fire include ground fires that burn the organic layers of the soil, surface fires that burn just above the ground, crown fires that burn in the canopies of trees, and mixed fire regimes where fires vary in severity with both surface and crown fire patches. Ground fires occur only in peaty soils in which they can be extremely damaging, destroying roots and completely altering soil properties. Crown fires are high severity fires typical of low productivity sites including Mediterranean-type shrublands, and North American boreal forests. Surface fires are common in many woodlands and forests where litter is a major fuel. Surface fires with herbaceous fuels predominate in grasslands and savannas and can burn at annual or even subannual intervals where productivity is high. When crown fires do occur in forests, they produce massive stand-replacing fires. Fire exclusion in national parks, such as the giant sequoia forests of California, has led to an increase in young trees which now act as bridging fuels turning surface to crown fires with extremely damaging consequences.

Fire frequency is estimated from maps of fires, records of fire scars, or patterns of charcoal deposition in sediments. The mean and variance of fire return interval are important descriptors of historical disturbance patterns. Changes in fire frequency are an important cause of changes in ecosystem structure and function. Fire intensity is measured as energy released per meter of fire front. It is widely used in firefighting operations. Fire severity is a distinct but related concept defined as the ecological impact of a single fire and usually estimated from the amount of plant biomass consumed. A fast-moving fire that consumes little biomass and a slow-moving fire that consumes more can have the same fireline intensity but different severity. Fire severity is highly variable, literally depending on the weather during a burn, wind conditions, and the preburn condition of the vegetation. Fire season is largely dictated by the moisture content of flammable biomass. Where the vegetation dries out quickly, fires can burn in almost any season. Seasonal timing of burns can cause significant changes in species composition and ecosystem structure. Continuity of flammable vegetation, especially at the landscape scale, strongly influences the spread of fires. Habitat fragmentation can lead to a reduction in fire frequency of isolated fire-prone ecosystems or an increase in fire-excluding forests surrounded by flammable vegetation. Land abandonment in some countries has led to successional changes producing large, contiguous, highly flammable vegetation. In the Mediterranean region, reduction of pastoral activities has led to the conversion of grasslands to highly flammable shrublands. This process has contributed to an increase in the area burnt annually from a few thousand hectares in the 1960s to hundreds of thousands of hectares in recent years.

Fire Regimes and Phytogeography

Flammable ecosystems differ greatly from one another in the mix of growth forms and their fire-adaptive traits. This diversity is linked to differences in fire regime. Fire regimes are the

product of a synergy between external physical factors and the properties of vegetation. In the absence of humans, key physical preconditions for wildfires were climatic conditions conducive to lightning strikes, periods dry enough for ignition to occur, and enough oxygen in the atmosphere to sustain burning. Where fire influences the geography of plant communities, another physical precondition is landscapes free of major barriers to fire spread. Such barriers include rivers, lakes, ice and snow, gravel beds, and other areas with sparse plant growth. Within these physical constraints, the vegetation itself is the major contributor to the fire regime.

The way in which the plants themselves contribute to the fire regime is most apparent where contrasting ecosystems, with entirely different fire regimes, occur in the same landscape. These have been described as alternative stable states with each ecosystem state maintained by a different set of positive feedbacks. Examples include mosaics of fire-resistant tropical forests and flammable savannas occupying extensive areas of Africa, South America, and Australia. In some instances, mosaics of alternative ecosystem states occur where both states are flammable but with contrasting fire regimes. In western North America, for example, chaparral shrublands with crown fire regimes occur in landscape mosaics with conifer forests with litter-fueled surface fire regimes. Changes in the fire regime can be brought about by changes in external conditions, such as climate change, but also by changes in the growth form mix, producing changes in flammability or productivity. The shortest interval between successive fires is constrained by the time taken to build sufficient, continuous flammable biomass for fires to spread. This depends on the plants present and site productivity. Changes in plant growth form dominance can have major impacts on fire regimes such as those caused by introduction of highly flammable invasive grasses into shrublands and woodlands.

Species Response to Burning

Plants

Ecosystems subjected to similar fire regimes have convergent vegetative and reproductive traits. There are clear distinctions, for example, between fire-adaptive traits characteristic of crown fire regimes fueled by woody plants as opposed to surface fire regimes fueled by litter or herbaceous plants (Keeley *et al.*, 2012). In crown fire regimes, a fire event triggers flowering, seed dispersal, or seed germination in fire-dependent plant species. Fire-stimulated flowering is common among perennial grasses and herbs, including orchids, lilies, and other bulb plants. These flower prolifically after they have been burnt with some species showing a facultative response (continuing low levels of flowering in unburnt vegetation) and others an obligate response with flowering cued by smoke (e.g., *Cyrtanthus* spp. in Africa, *Xanthorrhoea* in Australia). Fire-stimulated recruitment also occurs when fires stimulate seed release from woody species with serotinous cone-like structures which store seeds on the plant for years between fires. Serotiny is common in conifers of North American boreal forests and Mediterranean-climate regions and also among diverse groups of flowering plants in Australia and South

Africa. Some species are polymorphic for the trait, with serotinous forms increasing in populations that regularly experience large severe crown fires. Fire-stimulated seed germination from soil seedbanks is also common in crown fire regimes. Dormant seeds in the soil show heat-stimulated seed germination, especially in legumes and other clades with hard seed coats (e.g., members of Rhamnaceae). Thick seed coats prevent imbibition of water until cracked by the heat of a fire. Smoke-stimulated seed germination has been reported for many species in fire-prone shrublands of South Africa, Australia, and California. However, smoke-stimulated germination has also been reported for plants that do not come from fire-prone ecosystems. Regardless of the nature of the germination cue, the appearance of numerous seedlings after a fire event is characteristic of fire-dependent species in ecosystems with an evolutionary history of crown fire regimes.

Vegetative features of plants also vary with fire regime. Thick bark and/or the ability to resprout from insulated buds allow many plants to survive burning. Sprouting is a common fire survival mechanism, either from the root stock or from branches above the ground. Some species possess large swollen burls or lignotubers which are thought to act as bud banks or storage reserves. Paradoxically, many woody plants in crown fire regimes cannot resprout and are killed by fire. These nonsprouting plants often have higher seed production and higher seedling growth than related sprouting species. In some lineages, sprouting is the ancestral feature and loss of sprouting is viewed as an adaptive response to fire. Nonsprouting shrubs are particularly common in chaparral and similar shrublands and require fire to release seeds from serotinous cones or to stimulate germination. Among trees in fire-prone forests, many conifers do not sprout and a few eucalypts are also killed by fire. Nonsprouting species are particularly prone to local extinction if recruitment fails after burning.

The occurrence of species with flammable morphologies in crown fire regimes has led to the suggestion that flammability has evolved to promote burning. However, vegetative traits that promote flammability may also serve other functions. Some woody plants accumulate highly flammable fuel by retaining dead branches while also requiring fire for recruitment. In western North America, serotinous pine species retain dead branches and recruit seedlings only after crown fires have destroyed the trees. These species appear to both promote the spread of crown fires and benefit from fire-stimulated reproduction. This strategy contrasts strongly with self-pruning, thick-barked pines (e.g., *Pinus ponderosa*) which tolerate frequent surface fires and do not require fire for seedling recruitment.

Surface fire regimes fueled by herbaceous plants select for a completely different suite of plant traits. Grasses are among the most fire resistant of all plant growth forms. The buds of new shoots are insulated by either layers of leaf sheaths or the soil where species have underground rhizomes. Grasslands recover from burning more rapidly than woody plants and can carry very frequent fires (1–3 years) in productive sites. Although many grasslands burn readily, few species have an obligate dependence on burning. Fire-stimulated flowering is rare but has been reported in many mostly temperate tussock grass species, including species of *Chionochloa* in New Zealand.

Several very widespread warm-climate (C4) grasses (e.g., *Themeda triandra* and *Andropogon gerardi*) decline rapidly in the absence of burning. These species become locally extinct if fires are suppressed for more than a decade since litter accumulates, shades, and kills the grass plants. Unlike crown fire systems, all woody plants in savannas resprout after fire and seedling recruitment is not fire dependent. Instead, savanna trees have developed a remarkable ability to tolerate very frequent grassland fires. These create a particularly hostile environment for juvenile stages. Tree seedlings survive by rapidly acquiring the ability to sprout, and juveniles slowly develop food reserves in swollen roots and eventually produce bolting stems that place foliage above flame height. This peculiar life history occurs in several pine species (e.g., *Pinus palustris*) growing in grassy habitats and also in many savanna trees. A tropical Asian species, *Pinus merkusii*, produces persistent sprouting juveniles in frequently burnt populations but nonsprouting forms in infrequently burnt island populations. Juvenile stages of savanna trees can tolerate repeated burning, suffering repeated killing of the stem parts, for decades before they die or escape the flame zone to become adults.

Animals

The direct effects of fire on wildlife are often surprisingly small. Agile animals flee to unburnt refugia, moving across the fireline to places of safety. Soil is a very effective insulator so that many animals survive in crevices and cracks or in burrows in the soil. Mortalities of large mobile vertebrates, including humans, do occur but only in the most severe fires. Reptiles and slow-moving invertebrates can suffer higher mortalities and their carcasses provide a food source to scavenging birds and other creatures in the first few days after a burn. The threatened bald ibis of South Africa makes extensive use of recently burnt grasslands, as does the endangered whooping crane in its Texan winter feeding grounds.

The indirect effects of burning are generally far more important than fireline mortality, especially changes in habitat attributes as vegetation recovers from a fire. A large crown fire in a forest causes drastic structural change and local extirpation of all faunal elements that depend on unburnt forest habitat. Postburn stages are colonized by a new suite of species. Different successional stages support different suites of animals. Even frequently burnt grasslands, such as those of the South African highveld, have distinct bird assemblages which turn over with successive years of regrowth after burning.

The pattern of fires across a landscape imposes a mosaic of patches of different successional ages. The size and configuration of patches influence rates of local extinction and patch recolonization (metapopulation structure). For example, nectar-feeding birds in shrublands of Australia and South Africa lose their food source, shrubby members of the Protea family, after a burn and have to seek unburnt stands for food. The landscape configuration of old stands with flowering proteas, and young stands with immature shrubs, necessitates a highly mobile bird assemblage. Changes in the spatial pattern of fires may change extinction risks in different faunal elements. Some species of Australian honeyeaters are threatened with extinction because changes in the fire regime no longer produce the

right mix of mature and immature populations of nectar plants. The decline of many bird species in Australian savannas has been attributed to the development of homogeneous landscapes through the systematic burning of very large tracts of land. Smaller, patchier burns are thought to have prevailed under aboriginal burning practices. The extinction of many Australian small to medium-sized (50 g to 5 kg) mammals since European settlement (23 species) has been attributed to similar changes in the fire regime, but predation by feral animals is a major factor.

Fires in tropical rain forests, caused by human impacts on forest structure, have had devastating effects on the forest fauna. In Sumatra, for example, primary forest specialists, including squirrels, hornbills, and other fruit-eating and frugivorous birds, and some primate species disappear altogether from burnt and adjacent forests. The increasing risk of fire in humid tropical forests poses serious threats to survival of the forest fauna in addition to those caused by direct forest clearing.

Ecological Effects of Fire

Ecosystem Structure

The consequences of increasing fire frequency and severity for ecosystem structure are to reduce vegetation height (tall forests to shorter ones and woodlands to shrublands); to replace woody vegetation by grasslands; to promote flammable species or communities (low litter decomposition rates, more xeromorphic leaves, and finer twigs/branches); and to reduce biomass. Both tropical and temperate landscapes contain mixtures of fire-prone grassland or shrubland communities and closed forests which tend to exclude fire. Savannas and closed forest are well-studied examples of such alternative ecosystem states. The relative proportions of flammable savannas and fire-resistant forests vary across precipitation gradients and, locally, with soil type. Boundaries between states are typically abrupt with fires excluded from forests, which shade out grasses. In some instances, paleoecological studies have shown that these sharp boundaries have remained stable for millennia. Simulations using physiologically based global vegetation models suggest that forests would at least double in extent in the absence of fire, particularly in the flammable savanna biome. Replacement of flammable communities by fire-resistant forest elements frequently occurs when fires are suppressed. In southern Africa, forests have replaced savannas after 10–30 years of fire suppression. However, counterexamples exist in which fire suppression does not lead to changes in savanna/forest boundaries. Stable boundaries often coincide with different soil types, with forests occurring on the better drained or more fertile soils.

Changes from fire-resistant to flammable ecosystems may also be rapid. In the Brazilian Amazon, fires in closed-canopy forests spread as a “thin, slowly creeping ribbon of flames a few tens of centimeters in height.” Despite the low severity of an initial fire, burning causes structural changes, opens up the forest canopy, dries out the understorey and contributes to an increase in flammable understorey biomass, increasing the risk of a second fire. Weedy vines and grasses quickly colonize

twice-burned forests, further adding to the flammable biomass. Positive feedbacks of this kind are estimated to reduce a forest to scrubby vegetation resembling recently abandoned farmland in 20–30 years.

Ecosystem Function

The immediate effect of fire is gaseous loss of carbon and nitrogen from material that burns. More biomass burns in more severe fires and the nutrient losses are greater. Strong winds accompanying fire lead to losses of phosphorus and cations blown away in ash. Cation nutrients in ash tend to be mobile and in a plant-available form. Their presence leads to increases in soil pH – large increases in acid forest soils and smaller increases in neutral or alkaline soils in grasslands or savannas. Increased solar radiation, decreased evaporation, and higher pH lead to increased microbial activity, increased rates of mineralization, and increased availability of nutrients after a burn. After a chaparral burn, for example, nitrate increased more than 20-fold relative to unburnt controls. Short-term increases in nutrient availability can be offset by long-term decreases where fire frequencies are high and inputs to the system between fires are not high enough to replace losses. Severe fires can lead to nitrogen shortages. Many ecosystems have nitrogen-fixing organisms as major components of postburn vegetation which replace nitrogen losses in a few years.

Fire can lead to changes in ecosystem processes at landscape scales. The reduction in biomass caused by burning and changes in soil properties lead to temporary hydrological changes in patterns of stream flow. Severe fires can lead to increased soil erosion. The Yellowstone fire of 1988 led to significant increases in sediment loads and altered the geomorphology of river systems. Debris spread over a distance of 12 km in one valley bottom.

Species and Populations

At the local scale, and within flammable ecosystems, species respond to differences in fire frequency, season, and severity. Variation in the fire interval is an important determinant of population trends. In crown fire regimes characteristic of woody fuels, the effect of fire on population growth depend on key demographic attributes of the species. Population size of nonsprouting species fluctuates more than that of sprouting species, and local extinction is not uncommon after a single fire. Species that are slow to mature are particularly vulnerable where populations are burnt before they have first flowered and set seed. Populations are also negatively affected where intervals between fires exceed the life span of a species or its seedbank. C4 grasses are also sensitive to variation in fire frequency with the dominant species in some grasslands disappearing after a decade or more of fire exclusion. The rich forb diversity in upland grasslands in Africa and South America is also dependent on frequent fires and fire exclusion has been shown to lead to loss of long-lived perennial species, especially those with large underground storage organs. This contrasts with North American prairies where fire exclusion promotes forb diversity. Manipulation of the fire interval is a

key tool for influencing biodiversity of vegetation stands. In flammable woody ecosystems, information on the reproductive status of plants, especially the size of the viable seed-bank, at different postburn stages has been extensively used to help determine optimum fire frequencies to maintain particular species.

Recovery of plant populations also depends on the unique combination of circumstances on the day a fire burns. These “event-dependent” effects can be as important as fire frequency in influencing biodiversity in some ecosystems. Fire season has a marked influence on recruitment of serotinous members of the Proteaceae in Western Australia and South African fynbos. Spring burns can reduce protea populations to less than one-tenth of their preburn density, whereas autumn burns can result in a 10-fold or greater increase in plant densities. Fire season also influences recovery of sprouting plants where the size of root reserves varies seasonally, affecting the vigor of resprouting. Manipulation of fire season is sometimes the only effective tool for managing densities of sprouting shrubs. Stem density of clonal species of hazel (*Corylus* spp.) in the understorey of temperate forests increased fivefold with four successive spring burns but was halved by successive summer burns. In Zambian woodlands, annual burns in the early dry season caused a 10-fold increase in tree seedlings and halved the adult mortality rate over a decade. Grassland composition can also be very sensitive to fire season. In a long-term burning experiment in the Kansas prairies, late-spring burns caused a halving of *Andropogon scoparius* biomass relative to fires burnt a few weeks earlier. The effects of fire season on species and ecosystem recovery are poorly known in many ecosystems. They may be unimportant where the fire season is short because of climate constraints.

By definition, severe fires cause the most extreme biomass losses in ecosystems. In eucalyptus and conifer forests, intense crown fires kill all aboveground plant growth. Where trees are incapable of sprouting, these fires cause complete replacement of canopy trees. Sprouting plants, especially shallow-rooted species, can be killed by high severity burns. The effects of fire severity on recruitment from seeds vary among species. Legumes and other plants with hard, dormant seeds in fire-prone shrublands do not germinate unless a burn heats the soil sufficiently. For example, the Australian shrub, *Acacia suaveolens*, will not germinate unless soils are heated to more than 50 °C. Variation in fire intensity can directly affect species composition in fire-prone shrublands, incinerating some seeds and stimulating germination in others. Key species, such as legumes, may fail to germinate after low-intensity fires that are applied for safety reasons.

Fire intensity is an important factor in savanna ecology. Where grass growth is sufficient to carry fires at frequent intervals, burning kills the aboveground parts of juvenile trees and shrubs. The amount of dieback depends on the intensity of the burn. In mesic savannas, fires are so frequent and so intense that juvenile trees may spend decades trapped in the grass layer. The frequency and intensity of fire are important determinants of tree biomass (and habitat structure) in savanna ecosystems.

The relative sensitivity of plants to fire season and fire severity varies among species. This makes general prediction of population trends under different fire cycles difficult without

species-specific information. In Mediterranean shrublands, species with diverse responses to frequency, season, and intensity of burn occur in the same community suggesting a history of fires that vary in these factors. It is a considerable conservation challenge to incorporate variability into fire regimes to maintain the full diversity of species.

Interactions between Fire and Other Ecological Processes

Fire and Herbivory

Fire interacts with, and is influenced by, other agents of disturbance that can also influence ecosystem structure on a large scale. Herbivores influence the distribution and biomass of plants and therefore the attributes of fire regimes. Heavily grazed savanna grasslands do not burn so that animals capable of grazing grasses too short to burn, such as wildebeest, white rhino and prairie dogs, can reduce landscape fire activity. Extirpation of short-grass grazers can, in turn, promote more frequent larger fires reducing landscape heterogeneity. Persistent heavy grazing by cattle often leads to an increase in tree densities because of the reduction in fire frequency. In Africa, elephants open up woodlands, enhancing grass growth which promotes more frequent severe fires. The combination of elephants and grass fires can cause a marked reduction in tree densities. In miombo woodlands of Zimbabwe, changes in woodland structure under the combined influence of elephants and fire markedly reduced bird diversity and led to local extinction of four endemic woodland bird species.

Insect herbivory also influences fire regimes, especially in northern ecosystems. In Balsam fir (*Abies balsamea*) and red spruce (*Picea rubens*) forests of eastern North America, fires are rare. Large-scale tree mortality is caused by spruce budworm outbreaks which inhibit the spread of fire by changing vegetation structure and fuel properties. In general, however, plants that provide fuel for burning make poor food for herbivores and vice versa. Fires burn readily where decomposition is slow, causing dead matter to accumulate. Slow decomposition is associated with high C:N ratios, high fiber contents, and high leaf-specific weight, all of which inhibit herbivore food intake. Thus, the most fire-prone vegetation tends to be least edible and vice versa.

Fire and Landscape Fragmentation

The spread of fire in a landscape is sensitive to the continuity of flammable vegetation. Landscape fragmentation can have major impacts on the fire regime, in turn affecting survival of species within fragments. Species losses from North American prairie fragments during a 50-year period were greater among plants of early postburn environments. Similar patterns of local extinction occur in fynbos fragments surrounded by nonflammable forests in South Africa. The causes of species loss in both prairies and fynbos are attributed to infrequent burning due to isolation of the fragments. Small forest patches in extensive areas of fire-prone shrublands or grasslands are also more likely to suffer local extinction of species intolerant of burning. In the tropical forests of Guyana, fire-tolerant

forest tree species with thick, fissured bark, and small seeds are unusually common near savanna boundaries and human settlements.

Fire and Invasives

The interplay between fire and invasive species can cause alarming ecosystem transformation. Direct effects of invasive plants can be minor relative to the indirect effects on fuel properties and fire regimes. Grass invasion into woody ecosystems has particularly damaging consequences. In Hawaii, invasion of tall nonnative grasses has transformed the unique forests to grasslands entirely alien to the island ecosystem by fueling frequent fires. In South America, invasion of logged-over tropical forests by fire-promoting grasses can cause elimination of the forest ecosystem and its rapid replacement by the alien grass. In southwestern Australia, species-rich heathlands are fire dependent but they have also been invaded by nonnative grasses which burn so frequently that the heathlands are transformed into a species-poor savanna with scattered relictual trees. The reverse pattern, that of invasion of fire-prone grasslands by plants that do not burn easily, may also be a problem. For example, *Lantana camara* is invading fire-dependent grasslands in South Africa but burns much less readily than the native vegetation.

Managing Fires

Because wildfires are such a widespread feature of world vegetation, managing fires for particular objectives, including conservation of biodiversity, is a major concern. Attitudes and actions to wildfire are never neutral. Fires are actively suppressed in some ecosystems but purposely ignited in others. Wildfires commonly arouse public and media concern. The spread of the urban interface as more people flock to cities has increased threats of wildfire to people and properties. Smoke management has become a health and safety issue. Enormous effort and expense are often expended on fire management. Appropriate fire management policies continue to be a central management headache in protected areas as different as Yellowstone National Park in a coniferous ecosystem and Kruger National Park in African savannas. The expense of maintaining firefighting teams consumes a significant fraction of conservation agency resources. Litigation, when fires move beyond the borders of protected areas, can also strain conservation budgets. Arson burns are not uncommon, sometimes as a protest against state authority. Fire management consumes a great deal of time and is a major expense in fire-prone ecosystems.

Fire Management Policies

There is no consensus on how to manage fires in protected areas or outside them. For the first half of the twentieth century, complete fire suppression was a common policy, and it still is in many parks. Suppression policies have slowly changed, partly because of their cost, partly because they do not work, and partly because of changes in ecological

thinking. Fire suppression leads to the buildup of dead biomass in fire-prone ecosystems which produce very severe fires when they do burn. Suppression policies were also relaxed following the discovery of fire-dependent features of plants. In the Cape fynbos, the beautiful marsh rose (*Orothamnus zeyheri*) declined to a handful of plants before managers realized that the species had an obligate dependence on fire to stimulate germination of its seeds. There has also been increasing recognition of disturbance as a natural process in ecosystems. Outside of rain forests, complete fire suppression is rarely the aim of fire management. However, decades of suppression have led to pronounced changes in ecosystem structure that now pose major challenges regarding how to reintroduce fires without causing more problems. Many conifer forests were maintained as open parklands by frequent surface fires. Fire suppression has allowed numerous young trees to establish, creating “bridging fuels” and a switch from surface to crown fires which destroy the whole forest structure. In some savannas, fire suppression has led to invasion of grasslands by forest species in a process that is very difficult to reverse except by costly manual clearing of trees to restore large mammal habitat.

Prescription burns are fires intentionally lit for management purposes. Safety for the fire crew, and for property, is always an important consideration. Therefore, prescribed burns often cause significant changes to the fire regime, especially to season and intensity but also to fire frequency. Changes to the fire regime can lead to significant population declines in sensitive species such as legumes, which depend on intense heat for seed germination.

Prescription burning calls for clear management objectives. Because fire is so influential a force on community structure and composition, decisions have to be made regarding the desirable objective and what kind of burning pattern should be used to achieve it. In the South African savanna parks, fire policy changed from complete fire exclusion to prescribed burning at fixed intervals (promoting large mammals) to fire regimes that “maximize biodiversity.” The intention of the latter is to create and sustain a landscape mosaic of different successional ages or habitat types that can maintain viable populations of most species. What to do in practice is more difficult.

Another commonly considered policy is to recreate “natural” burning regimes. This policy permits fires that have been ignited by lightning, rockfalls, or other nonhuman agents but suppresses fires of human origin. It is difficult to apply in practice because vegetation has been fragmented by roads, buildings, croplands, and settlements so that fires can no longer spread unhindered across the landscape. Recreating natural fire regimes has also been criticized for not including aboriginal influences on fire regimes which may have significantly influenced landscape patterns over millennia. A variation on natural burning policies is therefore to recreate aboriginal burning practices to try to reproduce preagricultural landscapes. Implementation of these policies is constrained by lack of biological knowledge, techniques for fire management, and safety-related considerations.

In practice, fire management increasingly involves a mix of fire suppression, prescription burns, and controlled natural fires depending on safety concerns and conservation objectives in different parts of the landscape.

Fire and Global Change

Effects of Global Change on Fire Ecology

The impact of global change on fire regimes is likely to be quite different depending on whether fire activity is limited primarily by weather or by sufficient fuel to burn. Weather-dependent fires are characteristic of woody ecosystems such as conifer forests, eucalypt woodlands, and flammable shrublands. Fires in these ecosystems are most severe and burn the largest areas following long hot dry periods. In contrast, fires in grass-fueled ecosystems burn most extensively after unusually wet years. The implication is that climate change will have very different effects depending on the nature of the ecosystem. In the boreal forests of Canada, burned area has increased over the past half century. This is attributed to global warming with warmer temperatures generating larger fires (Flannigan *et al.*, 2009). Global warming in the circumboreal region is predicted to cause a doubling of area burned along with a 50% increase in fire occurrence by the end of this century. Similar dire predictions have been made for the conifer forests of Yellowstone with such frequent and severe fires that the forests may be eliminated and replaced by low biomass ecosystems by midcentury. Global warming might also increase the frequency of high severity fires entering tropical forests from adjacent savannas. However savannas, which currently account for more than half the world’s annual burnt area, are also influenced by other global change factors that might cause large reductions in fire activity. Climates are predicted to be drier for much of Africa resulting in less grass biomass to fuel fires. In addition, increasing atmospheric CO₂ may favor the spread of less flammable grasses than those that currently dominate these highly flammable ecosystems. Increasing CO₂ is also thought to be contributing to increased woody cover in savannas, and the expansion of forest into savannas despite frequent fires. Increasing human population densities are leading to fragmentation of fuels and reduction of burnt area through increased livestock densities, land conversion to crops, expanded road networks, and growing urbanization. The intrinsic properties of plants that fuel fire are also being altered by invasion of exotic species. Introduced grasses have promoted increased fire activity in many ecosystems but shrubs, such as *L. camara* and *Chromolaena odorata*, have reduced fire activity in others. Thus the future of fires, and of savannas, is very uncertain. Uncertainties in global change predictions for fire regimes are being addressed by the development of physically based fire spread models coupled with physiologically based global vegetation models that incorporate both climate and CO₂ effects on future vegetation. Ultimately, however, the challenge is to devise innovative fire management options that reduce risks to lives and property while maintaining landcover that meets diverse human needs.

Fire as a Source of Greenhouse Gases

Vegetation fires contribute significantly to greenhouse gas emissions thereby influencing global climate change. Satellite data have greatly improved estimates of global fire emissions but there are still many uncertainties, not least of which is interannual variability in fire activity. Global fire emissions

from 1997 to 2009 averaged $2.0 \text{ Pg C year}^{-1}$ compared with $\sim 7.2 \text{ Pg C year}^{-1}$ from fossil fuel combustion (van der Werf *et al.*, 2010). Major contributions to global fire emissions are from Africa (52%), South America (15%), Equatorial Asia (10%), the boreal region (8%), and Australia (7%). Savannas and grasslands contributed 60% of C emissions but most of these emissions would be compensated by rapid postburn regrowth. Annual emissions ranged from lows of 1.5 Pg C to a high of 2.8 Pg C in 1998, following an El Niño, with major fires in Indonesia. About a quarter of fire carbon emissions ($0.5 \text{ Pg C year}^{-1}$) were attributed to deforestation, burning of tropical peatlands, and degradation in the period 1997–2009 and are probably a net source of CO_2 to the atmosphere. Unlike savanna fires, deforestation fires also emit large quantities of reduced trace gases like CO and CH_4 . Deforestation, degradation and tropical peat fires together account for about half of global CH_4 (methane) emissions. Boreal peatlands are a major C pool storing as much as 270–370 Pg C. Increased fires, and a change from surface to ground fires, in boreal forests could potentially release enormous quantities of C into the atmosphere. The increasing frequency of fire in humid tropical forests is also of concern. Tropical forests are estimated to store one-fifth of the world's carbon. If burning of tropical forests continues, very large areas could be converted to flammable secondary scrub or grassland releasing this carbon into the atmosphere.

Fire is also an important source of aerosols. Aerosols decrease regional and global irradiation through backscattering of incoming solar radiation. Smoke aerosols can also increase or decrease cloud cover in complex and nonlinear ways that are not yet adequately quantified. Fire can also influence radiative forcing by altering the albedo. Black soot immediately after a burn heats the surface by reducing albedo. However, fire-induced reduction in tree cover can cause cooling by extending snow cover in boreal forests or replacing dark forests with more reflective vegetation (e.g., savanna grasses) elsewhere. The net effects of changing fire regimes on global warming are complex and uncertain. Public concern regarding atmospheric impacts of burning is leading to public pressure regarding the use of fire for conservation purposes. This may have positive effects if it leads to adoption of logging practices that reduce fire hazard in humid forests. Public pressure to suppress fires could have negative impacts on naturally flammable ecosystems and their fire-dependent species.

Glossary

Associational refuge When a potential prey escapes or deters a consumer by associating with another organism, that interferes with the ability of the consumer to locate or attack the prey.

Bottom-up effects When physical parameters (such as nutrients) allow increased primary productivity and the effects of this cascade up through higher trophic levels. A simple example involves nutrient additions to a lake resulting in increased phytoplankton growth, this increasing resource of food allowing increased number of herbivorous zooplankton, and the abundance of zooplankton leading to increased densities of zooplankton-eating fishes.

Coevolution Joint evolution of two (or more) interacting species, each of which evolves in response to selection imposed by the other.

Competitive release The expansion of a species-realized niche that is associated with the absence or removal of competition from other species.

Grazer A consumer that removes only a part of each prey it attacks and thus rarely kills a prey in the short term. The term is commonly applied to animals that eat plants (herbivores) but can also be argued to apply to nonlethal microbial pathogens and to animals that cause tissue loss, but not death, when they feed from colonial animals such as sponges.

Resource partitioning When organisms differentially utilize resources such as food, space, or nutrients.

Secondary metabolite An unusual compound that does not play a role in primary metabolism (e.g., production and storage of energy). These metabolites were initially argued to be waste products but have often been shown to defend the producer from consumers, pathogens, or competitors.

Top-down effects When feeding by higher trophic-level organisms has cascading effects on lower trophic levels. A simple example is when fishes (predators) consume zooplankton (herbivores) and, by lowering the numbers of these herbivores, allow increased densities of photosynthetic phytoplankton (primary producers).

Introduction

Herbivores play a major role in determining plant biodiversity by strongly affecting distribution, abundance, and community organization. Because plants are the major primary producers and often constitute the major biogenic structural complexity around which other community members are organized, effects of herbivores on plants commonly produce strong indirect effects on other trophic levels and on the biodiversity and function of the ecosystem as a whole.

Because almost all the energy on Earth is fixed *via* plant photosynthesis, it is an evolutionary mandate that higher trophic levels will need to consume plants and that successful plants will need to resist, tolerate, or escape herbivores, pathogens, and other natural enemies. Humans are dependent on plants for food, clothing, shelter, fuels, pharmaceuticals, and other necessities; thus, we often compete with other consumers (e.g., insect herbivores and pathogens of crop plants) for desirable plant resources. Owing to this continuing struggle to grow and harvest plant resources, plant-herbivore interactions are one of the more intensively studied areas in ecology, evolution, and agriculture. Research on this topic provides a rich resource for evaluating the effects of grazing on biodiversity. In numerous instances, examples from both marine and terrestrial studies show similar patterns. However, because of the more rapid growth of marine plants, the more intense grazing by marine herbivores, and the greater ease of manipulating seaweeds versus trees or shrubs, some of the clearest examples investigating the mechanisms of how herbivores affect plants are from marine communities.

In subtidal marine communities such as coral reefs or kelp beds, it is not uncommon for herbivores to be one of the primary forces determining the distribution and abundance of plants and often the species composition and diversity of the entire community. For example, herbivory by fishes or sea urchins on coral reefs keeps reefs largely devoid of macroalgae and allows corals to flourish by reducing competition from rapidly growing seaweeds, several of which produce chemicals that damage corals on contact. When these herbivores severely declined on the Caribbean island of Jamaica due to a combination of overfishing and urchin disease, coral reefs suffered severe overgrowth by seaweeds, and coral cover declined from more than 50% to less than 5% throughout this entire island nation (**Figure 1**). Thus, removing herbivores from these habitats converted species-rich coral reefs into a completely different community dominated by a limited number of seaweeds. Unfortunately, this pattern is not limited to Jamaica, coral cover has declined about 80% Caribbean-wide during the last three decades, and this pattern of rapid coral decline now seems to be occurring world-wide through interactive effects of global change and overfishing of reef herbivores.

Equally dramatic changes occur in temperate systems. Numerous ecological and paleontological studies have shown that subtidal communities in the temperate eastern Pacific shift from sea urchin-grazed barrens to lush kelp beds depending on the presence or absence of sea otters, which selectively forage on herbivorous sea urchins, reduce grazer biomass and allow kelps to flourish. If otters are removed from kelp communities due to hunting or predation, urchin densities increase, urchins drive kelps to local extinction, and

Figure 1 Large-scale changes in percentage cover of live coral at fore-reef sites along >300 km of the Jamaican coastline between 1977 (hatched bars) and 1993 (solid bars). For the island as a whole, coral cover decreased from 50 to <5%. Reproduced with permission from Hughes (1994) *Catastrophes, phase shifts, and large-scale degradation of a Caribbean coral reef. Science* 265: 1547–1550. Copyright 1994 American Association for the Advancement of Science.

fishes, kelp-associated invertebrates, and seals or sea lions that feed on kelp bed fishes also decline dramatically. Thus, in the tropical example, grazers increase diversity by removing seaweeds and allowing corals to produce the biogenic structure that enhances reef biodiversity, whereas in the temperate system grazers directly remove the major biogenic structure (kelps) and cause a decline in overall biodiversity.

Herbivores can also cause major alterations in terrestrial communities. When myxomatosis eliminated rabbits in Britain, many grasslands reverted to scrub woodlands. Similarly, it is argued that grazing elephants damage trees and change closed woodlands or thickets into grassy savannas.

The previously mentioned instances are among the most dramatic examples of herbivore effects, but they serve to show the effects that grazing can have on biodiversity and community structure and to point out that there should be strong selection for plant traits that deter feeding by herbivores.

Grazers as Disturbance Regimes

Charles Darwin noted that one grass species tended to dominate and exclude other species in unmown areas of his lawn, but that numerous species coexisted in areas that were periodically mown. He recognized that grazers might play a similar role in diversifying plant communities by preventing a few rapidly growing species from competitively excluding others. In the late 1970s, Joe Connell formalized this relationship when he demonstrated for both tropical rain forests and coral reefs that intermediate frequencies or intensities of disturbance could lead to coexistence of a larger number of species. When disturbances were severe and frequent, only a limited number of hardy species could occupy a habitat. When disturbances were too infrequent or weak to remove

competitive dominants, superior competitors tended to dominate. However, when disturbances occurred at intermediate levels, they removed enough of the competitively superior species to allow invasions by others but were not so severe as to prevent the occurrence of less hardy species. Thus, these intermediate levels of disturbance promoted the maintenance of greater biodiversity within a given community type. One of the most omnipresent forms of disturbance to plant communities is grazing, and it can play the diversifying role suggested by Connell. However, the effects that grazers have on plant biodiversity may also depend on the productivity potential of the environment. A recent review of how grazing affected plant diversity used data from a diverse range of marine, terrestrial, and fresh-water communities and found that grazing almost always increased plant diversity in environments characterized as having high nutrients (and presumably high potential growth rates), but often decreased diversity or had no effect on diversity when the environment was nutrient poor. These findings can be argued to mean that there are important grazer–nutrient interactions that need to be factored into the intermediate disturbance model. Alternatively, these findings simply mean that a given level of disturbance is “high” if it occurs in a habitat in which growth rates (and thus the ability to recover from the disturbance) are low, but it is “intermediate” if it occurs in a habitat in which rapid growth allows quick recovery.

As an example of intermediate grazing diversifying plant communities, work by Hixon and Brostoff (Figure 2) demonstrated that fish grazing rates on open areas of coral reefs were so intense that only the most resistant (coralline algae, which are red algae that resemble a thin calcified paint applied to a rock) or most tolerant (small filamentous algae that have basal sections embedded in the coral and that grow very rapidly) seaweeds could persist. In contrast, when fishes were

Figure 2 (a) Diversity, as measured by the Shannon–Weiner index H' , of algae on settling plates as a function of exposure time to three treatments: caged, inside damselfish territories (In), and outside territories (Out). (b) Diversity after 1 year (same data as in a) as a function of the intensity of fish grazing. (c) Graph of the intermediate disturbance hypothesis showing that consumers can enhance local diversity by increasing predation intensity from point 1 to point 2 or by decreasing overall predation intensity from point 3 to point 2. Copyright 1983 American Association for the Advancement of Science.

excluded by cages, substrates were dominated by a few species of competitively superior macroalgae. However, in defended territories in which damselfishes drove most other herbivores away, bite rates on the substrate were intermediate between those experienced on open versus caged substrates, and at these intermediate rates of herbivory there were many more species of seaweeds. Similar patterns have been documented in Mediterranean grasslands in which plant species diversity is maximized if livestock densities are maintained at intermediate levels.

Direct Versus Indirect Effects

Grazers may indirectly affect biodiversity *via* trampling, tunneling, seed dispersal, nutrient regeneration, and selection for plant traits that have cascading effects on other processes. As herbivorous prairie dogs dig their burrows, they create patches of newly disturbed ground that can be colonized by plant species that are rare in undisturbed habitats. Their activities also create mosaics of vegetation structure and nutrient status that result in both buffalo and antelope differentially using centers or edges of prairie dog colonies versus areas remote from colonies. Prairie dogs also clip inedible bushes to low heights so that the bushes do not provide ambush sites for predators or obscure the prairie dog's field of view. Lowering bush height decreases competitive effects and allows increased coexistence of other plants. As animals graze, they release nutrient-rich urine and feces back into the environment; this release affects nutrient dynamics, the spatial patchiness of plant production, and thus plant diversity. Such effects occur in habitats ranging from open-ocean gyres to African savannas and livestock rangelands.

Initial feeding on plants can also produce a cascade of indirect effects on habitat parameters or plant traits that then affect use by other species. For example, when infestations of beetles feed on goldenrod, they not only affect their target plant but also their activities alter light penetration to the ground, soil water content, and soil nitrate content. Following these changes in the physical habitat, areas near attacked goldenrod are invaded by other plant species, increasing local biodiversity. These indirect effects also occur in marine systems. When the seaweed *Fucus vesiculosus* is attacked by the specialist smooth periwinkle, *Littorina obtusata*, it induces greater chemical defenses; these defenses are not induced when it is attacked by the generalist common periwinkle, *Littorina littorea*. Because *Fucus* serves as food and habitat for numerous grazers, chemical changes in response to one herbivore could affect many others, which occur in this instance. The induced plants are less palatable to three other consumer species, and less frequently colonized by these species in the field. Thus, one consumer had a negative indirect effect on a second, co-occurring consumer *via* induced changes in a shared host. Indirect effects like these are likely common in all ecosystems.

The Roles of Spatial and Temporal Scales of Grazing

Many investigations of herbivore effects on diversity have concentrated on the maintenance of within-habitat diversity due to selective feeding on dominant plants or on the effects of small-scale disturbances that create patches and produce numerous successional states within a single community. In contrast to these studies, several investigations from marine systems show that species richness of seaweeds is often maintained by mosaics of herbivore impact that are relatively predictable in space and persistent in time. Many seaweeds are predictably found only within certain physical habitats. This restricted distribution was initially assumed to be due to physiological limitations or to fine-scale resource partitioning along physical gradients; however, experimental

studies demonstrated that many of these restrictions were herbivore induced and did not result from habitat partitioning based on competitive interactions or differing physiological requirements. When spatial variations in herbivory are experimentally reduced, habitats that differ dramatically in seaweed composition often become more uniform, usually resulting in a lowering of total species richness due to the loss of between-habitat diversity. In most cases, species that dominate following herbivore removal are palatable species that exclude, or significantly reduce the abundance of, herbivore-resistant plants. This is consistent with the hypothesis that the evolution of antiherbivore defenses can be achieved only by diverting energy and nutrients from other needs. Thus, defenses appear to be costly, and in the absence of herbivory, less defended individuals or species will have higher fitness than more heavily defended individuals or species. This relationship is depicted graphically in **Figure 3**. When herbivores are rare, plant communities are dominated by competitively superior, but palatable, plants. When herbivores are common, defense is favored over rapid growth and competitive ability. Under these conditions, communities become dominated by unpalatable plants that depend on the herbivores to remove better competitors. If herbivores selectively graze competitive dominants, they tend to free resources for other species and increase biodiversity. However, if herbivores selectively graze competitively inferior species, they may hasten local extinction of poorer competitors and lower biodiversity. This latter scenario appears to be relatively uncommon.

In the following sections, we discuss how herbivores affect plant diversity over a range of spatial scales. Patterns occurring over a scale of hundreds of kilometers are called geographic patterns. Patterns that occur over a scale of several meters to many kilometers and involve habitats that clearly differ in physical traits are called between-habitat patterns. Patterns occurring over only a few meters and within areas that appear relatively homogeneous are called within-habitat patterns. Patterns on a scale of centimeters or millimeters are called microhabitat patterns.

Figure 3 The hypothesized relationship between plant abundance and herbivore effectiveness for palatable and unpalatable plants. (a) Inedible or defended plants; (b) palatable plants with a refuge; (c) palatable plants without a refuge. Spatial patchiness of herbivory within a habitat allows multiple points on the x-axis to exist within the same habitat, thus increasing local biodiversity. Geographic Patterns

Large-scale patterns in plant distribution are often assumed to be due to physical parameters such as temperature. However, numerous recent studies suggest that some portion of geographic constraints on both specific species (or phenotypes within species) and morphological types may be due to geographic variance in herbivory. Because rates of herbivory are higher at lower latitudes, one might predict that tropical plants would be better defended than temperate plants. The few direct tests of this hypothesis suggest that it is generally true. Recent investigations demonstrated that seaweeds from tropical reefs were significantly less palatable and significantly better defended chemically than the similar seaweeds from temperate reefs. Similarly, studies of many species of salt-marsh plants across latitudinal gradients demonstrated that individuals from lower latitudes were subjected to greater rates of herbivory and were less palatable to a range of common herbivores than individuals of the same species from higher latitude regions. An investigation of freshwater plants and grazers shows similar trends. These patterns suggest that herbivore-generated processes shown in **Figure 3** could function on geographic and local scales and could enhance global biodiversity by creating differing selective regimes across these latitudinal scales.

Because tropical herbivores encounter more chemically defended prey than do temperate herbivores, one might expect that tropical herbivores would be more tolerant of plant chemical defenses than would temperate herbivores. This contention has not been extensively tested, but initial tests of a few tropical versus temperate fishes, sea urchins, and marine crustacea are supportive of this hypothesis, but indicate that there may also be considerable within-region variance in both plant defenses and consumer tolerance for those defenses.

Between-Habitat Patterns

Near-shore reefs often support more seaweed biomass and a different community of seaweeds than offshore reefs. Although both physical parameters and herbivores differ between these habitats, field experiments demonstrate that these differences in seaweed community structure are determined to a significant degree by differential herbivore activity. Early studies in the Caribbean demonstrated that seagrass beds, unstructured sand plains, and shallow unstructured reef flats supported different plant communities than did immediately adjacent reefs. Although the different physical regimes of these habitats appeared to be an adequate explanation for the differing seaweed communities, caging and transplant studies demonstrated that removal of herbivores allowed a more homogeneous distribution of seaweeds across these different habitats and resulted in lowered biodiversity of the reef system as a whole. In several studies, seaweed species typical of shallow reef flats invaded and dominated deeper areas on the reef once herbivores were removed. For example, when large fishes were excluded from parts of a coral reef in Belize, large macrophytes that were typical of nearby reef flats (but normally absent from the subtidal reef) invaded in large numbers and significantly decreased the abundance of corals and herbivore-resistant seaweeds during a 10-week period. Once

barriers were removed, these 10 weeks of algal growth were totally consumed in less than 48 h. A common response in herbivore exclusion experiments has been for palatable seaweeds to competitively suppress or exclude less palatable (and presumably better defended) seaweeds or other space occupiers (e.g., corals), again suggesting a tradeoff between defense and competitive ability. Recent work of this type on the Great Barrier Reef demonstrated that excluding grazers also caused large fields of algae to establish in areas formerly dominated by corals and that these algal beds suppressed the recruitment and survival of corals.

Within-Habitat Patterns

By aggressively excluding other herbivores from their algal mats, territorial damselfishes generate patches of intermediate grazing intensity in which algal species richness, evenness, and diversity are increased relative to either areas that are available to all grazers or areas from which grazers are excluded by cages. Several species that are normally excluded from unprotected areas due to grazing are found only within these mats. Thus, these territorial herbivores create distinct biotic patches on an otherwise more homogeneous background, raising species richness of the community as a whole.

In a similar manner, predators can strongly impact the spatial patterns of habitat use by herbivores and indirectly create mosaics of grazing intensity. In streams, algal-eating minnows avoid both shallow areas where they are susceptible to terrestrial predators and areas near larger predatory fishes. In both cases, these behaviors create patches of increased algal mass separated by heavily grazed habitats with minimal algal mass. Similar mosaics are created in terrestrial habitats when desert rodents forage more heavily under bushes than they do in more open areas where they are more exposed to predators. Within grasslands, excavating mammals, such as badgers, prairie dogs, and pocket gophers, provide newly bared soils for fugitive plants that are unable to successfully invade undisturbed plots. These within-habitat mosaics produce a series of successional states within the community and enhance plant diversity.

Microhabitat Patterns

In marine hard-substrate communities, small cracks and crevices serve as microhabitat escapes from some herbivores. Under these conditions, herbivory on exposed surfaces may select for defended seaweeds, whereas selection favors competitive ability in cracks and indentations. Work in experimental microcosms has shown that algal diversity decreases with increasing numbers of herbivorous fishes when substrate is smooth, but species number changes little with grazer densities if the substrate is more topographically complex. Thus, the presence of microhabitat escapes provided spatial refuges for palatable species and prevented their exclusion from the system.

Some types of plants can generate microhabitat escapes. There are many instances in agriculture and in the plant-insect literature in which interspersed host plants with nonhost species interferes with the ability of insect herbivores to find or

effectively utilize their host. Spiny desert plants sometimes function as “nurse plants” where less well-defended juvenile plants escape grazing vertebrates until they become large enough to escape because of their size. Plankton communities also exhibit these associational refuges; herbivorous copepods may quit feeding on palatable species of phytoplankton when they are mixed with adequate densities of chemically noxious species.

The effects of associational refuges on species richness have been addressed experimentally in several marine communities. Numerous seaweeds that are commonly driven to local extinction by grazers persist in herbivore-rich communities by growing on or beneath their herbivore-resistant competitors. The brown seaweed *Styopodium zonale* produces cytotoxic compounds that deter feeding by Caribbean reef fishes and urchins. Numerous species of seaweeds are significantly more common near the base of *Styopodium* plants than several centimeters away. When the chemically deterrent plant is removed, these less defended species are rapidly removed by herbivores, decreasing local species diversity. When plastic mimics of *Styopodium* are placed in the field, they provide a partial refuge for palatable species but they are less effective than the real plants, suggesting that associational refuges are generated in part by the physical presence of a nonfood plant but that the plant's chemical repugnance makes the associational refuge more effective.

In temperate communities, palatable seaweeds can reduce losses to herbivores by growing on or near unpalatable seaweeds. Growing in close association with these unpalatable competitors drastically depresses the growth of palatable species, but the associational benefits, in terms of reduced herbivory, can more than offset this competitive cost. Thus, palatable species can be dependent on their unpalatable competitors to produce spatial refuges from herbivory and prevent their exclusion from the community. Both field and mesocosm studies indicate that removal of common unpalatable competitors can cause extinction, rather than competitive release, of associated competitors that are more palatable. These associational refuges were initially interpreted as arising from simple visual crypsis, but more detailed investigations suggest that chemistry plays a significant role.

As a final example, sulfuric acid can constitute up to 18% of the dry mass of brown alga *Desmarestia*; this concentration is sufficient to dissolve barnacles from coastal rocks when this alga is deposited in the intertidal by waves. In Chilean kelp beds heavily grazed by sea urchins, the palatable kelp *Macrocystis* cannot successfully colonize unless it invades an area encircled by *Desmarestia* plants, which appear to act as acid brooms that prevent urchins from entering the area.

The associational escapes discussed previously are opportunistic rather than coevolved. As such, they may be used by many organisms in a wide variety of situations. There are, however, more intimate associational refuges or defenses that may be coevolved. Many microbes are predictably associated with specific species of macroorganisms. Because of the broad ability of microbes to produce bioactive secondary metabolites, many host organisms could be coevolved with certain microbes because the microbes produce compounds that defend the host from natural enemies. For example, certain fungi infect host grasses, produce toxins, and by doing so make the

grasses much more resistant to herbivores. Similarly, marine cyanobacteria grow in host sponges and produce bioactive secondary metabolites that can protect the host. There are also instances in which marine bacteria that are specialized to certain host surfaces produce metabolites that chemically defend their host from microbial pathogens. In such cases, pathogens or consumers may be selective for specialized microbial associates that defend their host. Such associations could increase microbial diversity and the diversity of macroorganisms by allowing hosts to persist in new habitats, thus facilitating both the evolution and the retention of increased species diversity.

Host Chemistry as a Promoter of Consumer Diversity

On some tropical reefs, fishes have been reported to bite the bottom in excess of 150,000 times/m²/day. In these areas, small herbivores such as amphipods, polychaetes, and crabs (collectively called mesograzers because of their size) would live short lives if they occupied plants that were preferred by fishes. Selection should therefore favor sedentary mesograzers that live on and eat seaweeds that are chemically repellent to fishes. Patterns supporting this notion have been documented for divergent types of mesograzers in several of the world's oceans. In the temperate Atlantic, some herbivorous amphipods and polychaetes live in tubes, which they attach to the seaweeds they consume. These mesograzers selectively live on and feed from brown algae that are chemically defended from fishes. By living in association with these seaweeds, which are seldom visited by fishes, they lower their susceptibility to predation.

The hypothesis that sedentary mesograzers minimize predation by specializing on toxic hosts has been tested more broadly using (1) a specialist Caribbean amphipod that eats, and builds a mobile domicile from, a chemically defended alga; (2) several species of crabs and sea slugs from both the Caribbean and tropical Pacific that each live on and feed from only one species of chemically defended alga; (3) non-herbivorous amphipods that live on and build homes from only one species of chemically noxious seaweed; (4) a decorator crab that minimizes predation by selectively decorating with a seaweed that is chemically repellent to fishes; and (5) contrasts between the palatability and susceptibility to predation or parasitism of specialist versus generalist herbivorous insects. In all these cases, predation on, or palatability of, the mesograzers was reduced as a consequence of their association with chemically noxious hosts. Additionally, mesograzers were generally stimulated or unaffected by plant compounds that deterred feeding by larger herbivores or predators.

There are numerous examples indicating that seaweeds or sessile invertebrates that evolve effective defenses against reef fishes may become evolutionary targets for specialized mesograzers that can escape or deter their own consumers by evolving a resistance to these compounds and living on, feeding from, and in some cases morphologically mimicking or sequestering defensive compounds from their toxic hosts. Thus, once hosts effectively deter common fish predators, these hosts can serve as valuable spatial escapes from predation for small consumers that specialize on these noxious

hosts. As in many of the earlier examples, this creates spatial mosaics of selection within otherwise more uniform habitats and allows for the evolution and retention of more species within the system.

The Potential Importance of Paleo-Patterns

Plant-herbivore interactions occurring today are the result of both modern ecological forces and an evolutionary history that has been operating for many millions of years. Major changes in plants or in herbivores can select for fundamental and often cascading changes in plant-herbivore interactions. For example, in modern African communities, grazing by elephants causes repeated deforestation of savannas, prevents larger plants from replacing grasses, and facilitates retention of other herbivore species that require open-grazing habitats. It has been hypothesized that loss of elephants and other megaherbivores from Europe and the Americas at the end of the Pleistocene may explain the dramatic loss of other grazing mammals in these regions. It can be argued that elephant grazing prevented open savannas from converting to woodlands and grazing by rhinoceros and hippopotamus prevented short grasslands from converting to less nutritious tall grasslands. The loss of these large grazers would have caused mosaics of parklike woodlands and grasslands to convert to more homogeneous forests and less productive tall grasslands. The loss of the mosaic vegetation structure is predicted to have caused the loss of numerous smaller herbivores that depended on spatial patchiness and the availability of nutrient-rich vegetation. This hypothesis is consistent with the variability in extinction seen among Africa, Eurasia, and the Americas and with the absence of extinctions at previous glacial-interglacial transitions.

The mass extinction of megaherbivores at the end of the Cretaceous also coincided with a dramatic change in the structure and species composition of the plant community. Most of the dominant ferns and cycads went extinct, but angiosperms and gymnosperms flourished. The decreased herbivory following the mass extinction should have allowed vegetation to become much denser, potentially increasing competition among plants. This change is hypothesized to have led to the evolution of larger seeds as a way of better provisioning juvenile plants. These larger seeds and the need for dispersal may have led to fruits for attracting animal dispersers. These abundant fruits and seeds are thought to have favored the evolution of small, fruit-eating birds and mammals that aided seed dispersal.

The cause-effect relationships hypothesized to have driven the paleo-changes discussed previously must be viewed with caution, given the general inability to rigorously test hypotheses associated with evolutionary time. However, it is clear that major changes in vegetational structure often coincide with extinctions of large herbivores and *vice versa*. There is also broadly accepted support for the notion that there has been an evolutionary arms race between vascular plants and their insect herbivores – the plants evolving chemical defenses against the insects, the insects responding by evolving resistance to some of these defenses and then tending to specialize on plants with those chemical signatures, and the cycle then

repeating. It is hypothesized that this diverse range of plant chemical defenses serves as a rich and heterogeneous resource gradient that has promoted the dramatic diversification of herbivorous insects.

It is tempting to assume that coincident changes in herbivores and plants are caused by reciprocal and evolved responses. However, such “co-evolved” responses may be difficult to differentiate from fortuitous preadaptations. One marine study with an especially complete fossil record provides an example. Encrusting coralline algae are highly calcified crusts that cover hard substrates and fossilize so well that grazing scars attributable to specific types of herbivores (i.e., gastropods, sea urchins, or fishes) are clearly preserved on their surfaces. These algae have left a long and abundant fossil record. Using fossilized corallines and information on present-day interactions between corallines and reef herbivores, one can convincingly argue that the evolution of herbivorous fishes (especially parrotfishes) dramatically increased herbivory on coral reefs and fundamentally changed the selective regimes affecting seaweeds on reefs and reef community organization in general. Coincident with these changes in grazing pressure, coralline crusts with numerous traits that minimized the effects of herbivorous fishes radiated dramatically while their assumed parent taxon (the solenopores, which lacked these traits) diminished in importance and eventually went extinct. From these coincident changes, it seems reasonable to assume that the escalation of grazing drove the evolution of corallines and selected for the numerous morphological traits that minimized the effects of herbivores on corallines. However, the exceptionally complete fossil record for the corallines allows this assumption to be tested. Virtually all the morphological traits that appear to be “adaptations” to grazing were present in the corallines before the evolution of macroherbivores and hundreds of millions of years before the evolution of parrotfishes. Thus, grazing fishes may well have driven the solenopores extinct and may have changed reef ecology to favor the expansion of the corallines, but the corallines were fortuitously preadapted for these changes – they did not adapt in response to them. Such examples should encourage caution in ecological interpretation of the fossil record.

Using Grazers to Manage and Restore Ecosystems

There is a long history of using grazers to maintain or restore ecosystem structure, function, or diversity. Both productivity and community composition can be affected by manipulating the duration, intensity, and timing of grazing. Herbivore manipulations have been used to increase species diversity, to increase the esthetic value of habitats, to preserve endangered species, and grazers appear to play roles in preventing invasions by exotic species, and to be useful in manipulations to restore community structure and function. Most grazers being used as management tools come from terrestrial grasslands, but this practice might also be useful in a wide variety of habitats ranging from forests and heathlands to coral reefs and lakes. In the following sections, we discuss some examples by habitat type or by critical process that occur across many community types.

Grasslands

Grazers are crucial to the maintenance of grasslands because without them there is an accumulation of plant litter that sequesters nutrients, physically limits vegetative growth, and interferes with seedling establishment. In a 10-year experiment focused on chalk grasslands in the Netherlands, sheep grazing helped rebuild species-rich grasslands that had been degraded due to agricultural use and heavy fertilization. When grazed and ungrazed plots were compared, the grazed plots had about 50% more species and the relative mass of forb was increased threefold. Studies of other grassland systems and grazers have produced similar results. For example, sheep grazing can be used to reclaim heathland from woodland by opening up vegetation, repressing growth of scrub, promoting low-growing plants, and encouraging growth of dwarf shrubs. Experiments with rabbits and bison show similar results. In both cases, when the grazers were removed from grasslands, plant diversity declined.

Although grazing increased biodiversity in the previously mentioned studies, several of these management efforts were designed to have this result, thus potentially providing a biased impression of how grazing will affect plant species richness. Under some conditions, grazers decrease biodiversity. Effects are likely to vary as a function of the evolutionary history of the plants and herbivores, the types of habitats investigated, the levels of grazing employed, and when and for how long these grazing regimes are maintained. As an example of the variable effects that grazing can have on producer diversity, a recent study reviewed 44 comparisons of plant species richness under low versus high grazing pressure in nutrient-rich versus nutrient-poor ecosystems. High rates of grazing reduced plant species richness in 100% of the nutrient-poor situations. In contrast, high rates of grazing increased plant diversity in 56% of the high-nutrient contrasts; diversity was unaffected by grazing in 36% of these contrasts and decreased by grazing in 8% of the contrasts.

Manipulation of herbivores can also be used to alter habitat traits, such as productivity, rates of nutrient cycling, and nutrient, water, and organic levels in the soil. In general, herbivores often increase organic breakdown and the mineralization of potentially limiting nutrients such as nitrogen and phosphorous. In the Serengeti, the aboveground productivity of moderately grazed plots is stimulated to about twofold greater than the productivity of ungrazed plots. In addition, ungrazed grass stands are senescent, whereas those grazed by large herbivores produce younger and more palatable shoots.

Although mowing can crudely substitute for some grazer effects, grazing will generally produce greater diversity due to spatial mosaics produced by patchy grazing (vs. even defoliation by mowing) and localized trampling. Selectivity and patchiness of grazing will also be affected by herbivore morphology and behavior. For example, teeth size and mouthpart morphology are important in determining the degree of selectivity exhibited by grazers. For example, cattle are less able to graze individual plants or plant parts than sheep, goats, or horses.

Fire has also been used as a surrogate for grazing or, in conjunction with grazing, to manage plant community

structure and species composition. This is especially true in attempts to prevent exotics and woody species from altering grasslands. Although fire may be a necessary disturbance in some systems, such as tallgrass prairie, fire alone is often not sufficient for restoration of biodiversity. After 9 years, in annually burned tallgrass prairie with nitrogen-addition, species diversity was 48% lower than it was 5 years before burning started and 66% lower than in unburned plots. In contrast, mowed, annually burned, nitrogen-addition plots had more than twice the species diversity than similar unmowed plots. Therefore, mowing prevented a decrease in species diversity that would have occurred with only fire and nutrient addition. When bison grazing replaced mowing, plots that were grazed and burned had the highest species diversity of all plots. Similarly, in a Mediterranean grassland study, cattle grazing led to an increase in species diversity, whereas burning resulted in no significant difference.

Forests

Many tropical forest trees produce large fruits that either fall near the parent tree or are dispersed by birds, primates, and other large mammals to sites remote from the adult tree. Dispersal is so critical for some of these species that their seeds require gut passage through dispersal agents before they can germinate. Because of the reliance on dispersers and the heavy predation on seeds near the parent canopy, it has been suggested that seed predators and dispersers are critical for maintaining tree species diversity in tropical forests. By selectively preying on seeds that fall near parent trees, specialized seed predators may decrease the survivorship of seeds near parents, preventing the occurrence of monospecific patches of forest trees and facilitating a more even and diverse assemblage of species. Because larger animals disperse the seeds of more than half of woody plant species, they play a critical role in removing seeds from sites of high predation and in introducing new species into different patches within a forest. The hunting, poaching, and habitat modifications that have left many forests depauperate in these animal dispersers have been suggested to be a cause of lowered plant diversity in tropical forests. If this is correct, then effective management of tropical forests may require the replenishment of large-bodied seed dispersers. In addition to grazing by larger animals, plants are also attacked by a diverse set of microbial pathogens and parasites. Recent investigations have shown that soil microbes may also play important roles in preventing monospecific patches. If microbes that attack a common plant build up in soils near that plant, they can lower the probability of that species' seedlings being successful in that site and thus promote diversity by favoring unrelated plant species in the vicinity of a long-established adult of a different species.

Livestock introduced to serve as seed dispersers can partially replace native dispersers that disappeared during the Pleistocene megafaunal extinction. The feeding activities of these introduced species can increase the range of some plants that produce large, fleshy fruits. In a lowland deciduous forest in Costa Rica, introduced horses and cattle feed on the fruits of jicaro (*Crescentia alata*) and disperse their seeds. In areas

with livestock, jicaro are common. In areas where livestock are absent, jicaro is relatively rare and occurs primarily in small, spatially restricted patches.

Many seed dispersers subsist exclusively on fruit for at least part of each year. This suggests that removal of seed dispersers by anthropogenic activities could have several repercussions. First, decreased seed dispersal could eventually lead to a decrease in the number of mature seed-producing parent plants. This would in turn lead to a decrease of important wildlife food resources, which could then lead to even lower numbers of seed dispersers. This situation can be especially critical if a particular tree species is pivotal in maintaining the health of dispersers during food-limiting seasons. For example, *Casearia* in tropical rain forests produce rich fruit during seasons of relatively low fruit abundance and likely supply much of the diet of local fruit-eating dispersers. In addition, this species supports frugivorous birds that are important dispersers of many other tree species during seasons when fruit is more abundant. The disappearance of animals that feed on *Casearia* fruits, leading to decreased recruitment of *Casearia*, could have far-reaching effects on the forest community. This scenario is thought to have occurred with jicaro. Frugivorous bats also feed on jicaro, and it is thought that a decrease in jicaro following the loss of Pleistocene seed dispersers led to a decrease in bats and then to a corresponding decrease in other fruit-producing plant species on which bats feed.

Lakes

Attempts to regulate the community composition of lakes have produced a mature science in which the separate and interactive effects of both physiochemical and biotic interactions are reasonably well understood and used in novel ways to manage lake ecosystems. Success in these systems has been achieved by fusing an understanding of biotic processes such as competition and predation (traditionally studied by population and community ecologists) with an understanding of the role of physiochemical processes (traditionally studied by limnologists and ecosystem ecologists). Investigations by Steven Carpenter and colleagues have been especially important in stimulating this field.

Problems of harmful algal blooms, fish kills, and general eutrophication of lakes have become increasingly apparent. Initial attempts to explain these problems, and lake productivity in general, as a function of nutrient levels revealed that nutrients could vary considerably in lakes with similar biotic communities and that nutrient levels (also known as bottom-up effects) explained only approximately 50% of the variability in lake productivity. This finding prompted lake ecologists to investigate the effects of trophic cascades (or top-down effects) in structuring these ecosystems. By understanding and manipulating both the bottom-up effects of nutrients and the top-down effects of consumers, lake ecologists have been remarkably successful at altering biotic communities and fundamental processes (e.g., productivity and nutrient cycling) occurring in lakes.

Because lake communities are structured by interactions between physiochemical conditions and biotic processes, initial attempts to manage lakes by managing nutrient input met

with only variable success. When the traditional focus on nutrients was merged with top-down manipulation of trophic structure, greater success was achieved in the control of lake phytoplankton populations and productivity. Mechanisms for this are as follows: As piscivore biomass increases, their feeding causes a decline in the biomass of small fishes that feed on herbivorous zooplankton; with the decline of these planktivorous fishes, the biomass of large herbivorous zooplankton increases and causes a decline in phytoplankton biomass and an increase in water clarity (**Figure 4**). In all these instances, productivity of each group is maximized at intermediate levels of piscivore biomass. This system of trophic cascades allows managers to affect planktivore, herbivore, or phytoplankton biomass and productivity *via* manipulation of larger fishes (which can be done using fish additions, removals, or common fisheries management practices).

Whole lake manipulations have shown that piscivorous fish populations can regulate planktivorous fish populations in both North American and European lakes. For example, in an experiment by Carpenter and Kitchell, one lake had a high bass (piscivorous fish) population and a small minnow (zooplanktivorous fish) population, whereas another had a low bass population and a high minnow population. Ninety percent of the large bass population was placed in the bass-deficient lake, and 90% of the large minnow population was placed in the minnow-deficient lake. When bass were added and minnows removed, the size of herbivorous zooplankton increased due to decreased predation. This led to decreases in chlorophyll concentration and primary production. In the opposite experiment, trophic interactions ultimately led to increase in chlorophyll concentration and primary productivity.

The interaction between trophic cascades and nutrient addition has also been addressed. In whole lake experiments in which phosphorus was added to lakes with a high or low density of piscivorous fishes, only a high density of piscivorous fishes was effective in maintaining low levels of palatable phytoplankton. The added nutrients increased the biomass of herbivores and colonial blue-green (unpalatable) algae but not the biomass of palatable algae. Grazers can control chlorophyll levels at phosphate loading significantly higher than loads that cause eutrophication. However, grazer control of undesirable blue-green algae appears to fail at phosphate loading rates lower than those used in this manipulation.

Figure 4 Effects of piscivore (= bass) biomass on biomass (solid line) and productivity (dashed line) of vertebrate zooplanktivores, large herbivores, and phytoplankton. Coral Reefs

Feeding by large generalist herbivores, such as fishes and sea urchins, is critical for maintaining the coral-generated topographic complexity that helps maintain biodiversity on tropical coral reefs. If these herbivores are removed, reef corals are competitively excluded by seaweeds. For example, overharvesting led to severely depleted populations of herbivorous fishes on coral reefs in Jamaica. However, the effects of overfishing were not fully realized for decades because the lowered numbers of predatory and competing herbivorous fishes allowed a build-up of herbivorous sea urchins that largely compensated for the declining fish grazing. When the urchin population was severely reduced by disease, macroalgal cover increased from 4 to 92%, severely overgrowing corals and inhibiting coral recruitment. The few grazers left on the reef (small parrotfishes and surgeonfishes) were not enough to control the algal growth, which has persisted for several decades. Recent work has demonstrated that seaweeds not only suppress coral recruitment, but numerous common seaweeds also damage (or sometimes kill) corals using surface associated chemicals that harm corals on contact. Thus, after disturbances like bleaching events, coral diseases, or storms that damage corals, the remaining corals may suffer additional declines due to contact with seaweeds. On overfished reefs such damage will be extensive and corals may decline further while seaweeds proliferate; on reefs protected from fishing, fishes prevent seaweed blooms and corals tend to recover. From scenarios such as this, it is evident that a higher density and diversity of grazers is required to decrease algal cover and allow coral recovery.

Manipulating these herbivores would therefore be a logical way to manage critical biotic processes on coral reefs. Because of the open nature of marine populations (i.e., the long-distance larval dispersal typical of most reef herbivores means that populations must be managed regionally rather than locally), this is a more challenging proposition than in the lake or grassland systems discussed previously. However, there is considerable evidence that degrading reefs recover, or degrade more slowly, when they are protected from fishing than when fishing is allowed to continue. The increased health of the protected reefs is correlated with an increase in herbivorous fishes. Recent experiments demonstrate that it is not only the abundance of herbivorous fishes that is important, but also the diversity. Different fishes consume different seaweeds and certain mixes of herbivore biodiversity are critical for preventing seaweeds from suppressing corals. On reefs in the Florida Keys, long-term enclosure of different herbivores on reefs demonstrated that herbivore diversity, independent of density and mass, was critical for suppressing seaweeds and facilitating coral survivorship and growth. Managing reefs to facilitate targeted herbivores that are especially important in removing reef macrophytes is a promising tool for aiding coral reef recovery.

Preventing Invasions by Exotic Plants (Data from Many Ecosystems)

Invasive species are a major threat to native biodiversity. Despite the widely held notion that plants become invasive

in new habitats because they have escaped their native herbivores, a recent meta-analysis of how native and non-native herbivores in numerous terrestrial and aquatic systems affected native versus nonnative plants found just the opposite. Native herbivores selectively attacked exotic plants, and exotic herbivores selectively attacked native plants. Exotic plants seemed to be succeeding because they were following rather than escaping their native herbivores. The documented patterns suggested that as humans invaded new continents, they killed off the native herbivores (thus preventing them from suppressing invasions by nonnative plants) and replaced them with nonnative, domestic herbivores (cattle, goats, sheep, etc.) that selectively attacked native plants. By removing native competitors, these exotic herbivores cleared the way for exotic plants from their own native region that were already evolved to live with these herbivores. These findings suggest that maintaining intact guilds of native, generalist herbivores may be effective in suppressing plant invasions and thus maintaining native plant biodiversity.

Summary

Coexistence of potential competitors within diverse plant communities has often been explained as a result of fine-scale resource partitioning. This is assumed to have resulted from an evolutionary history of competitive encounters and is usually inferred from shifts in abundance that occurs between habitats with different physical characteristics. Both marine and terrestrial plants show predictable patterns of distribution that can be interpreted as this type of habitat partitioning. However, manipulative experiments in marine systems, and to a lesser extent some terrestrial communities, show that many plants are habitat generalists and both between- and within-habitat patterns of distribution are often controlled by herbivores, or other natural enemies. Spatial patterns in herbivore effectiveness create a mosaic of habitats that differ in the degree to which they favor poorly defended but competitively superior species versus well-defended but competitively inferior ones. If herbivory is decreased, the mosaic nature of the habitat is reduced and many well-defended species are excluded by competition. This pattern occurs across a large range of spatial scales and can explain between-habitat differences in plant communities that occur hundreds of meters apart, within-habitat differences that occur only a few meters apart, and microhabitat differences that occur on a scale of centimeters or millimeters. A portion of the microhabitat pattern is created by the plants. For example, consumption of palatable plants can be significantly reduced when they grow on, or are intermixed with, unpalatable plants. These associational refuges increase species richness by allowing palatable forms to invade grazed areas after unpalatable forms establish and create microsites of reduced herbivory. At all of the scales examined, herbivore activities that promote spatial mosaics of herbivore effectiveness, or that differentially affect dominant plants, help to maintain higher biodiversity.

Foraging by herbivores is often constrained by factors (e.g., predation) that do not directly affect the physiological performance of primary producers. For plants, this differential use of space by herbivores often produces a spatial mosaic of selective regimes in an area that would otherwise be treated as one uniform habitat; this interaction commonly results in elevated species richness. The strong effects of herbivores on plants, and the strong effects of plants on community structure in general, mean that manipulations of plant–herbivore interactions can often be used as an effective management tool for promoting the maintenance of biodiversity or ecosystem function.

Glossary

Aerosols Microscopic airborne particles.

Albedo The fraction of light hitting a surface that is reflected.

Anthropogenic Resulting from human activities.

Climate sensitivity Long-term change in global mean surface temperature following a doubling of carbon dioxide (CO₂) concentration in the atmosphere versus its preindustrial (1750) level.

Earth energy balance Difference (if any) between incoming solar energy and outgoing terrestrial radiation for Earth as a whole.

Feedback Change in a system component that triggers effects that eventually change the original component again. Feedbacks can be positive (self-reinforcing) or negative (self-dampening).

Greenhouse gases Atmospheric gases that can absorb and re-radiate infrared radiation.

Litter Dead organic matter, such as leaves and branches, that is deposited as the top soil layer.

Radiative forcing Measure used to express and compare the potential of climate system changes (vs. preindustrial) to perturb the Earth's energy balance; reported in watts per square meter (W m⁻²). A positive radiative forcing tends to warm the Earth's surface and a negative radiative forcing tends to cool the surface.

Sink A physical reservoir of a compound that can take up additional quantities of this compound from the air and thus reduce its atmospheric concentration; for example, trees are a sink for CO₂.

Introduction

Earth's climate, from daily average weather events to glacial and interglacial cycles, is driven by the amount of radiation received from the sun and how that radiation is distributed throughout the global Earth atmosphere system. The atmospheric greenhouse effect acts as an important factor in establishing a temperature that is hospitable for life. The basic mechanism is simple and was first detailed by the Swedish physicist Svante August Arrhenius in 1896. Light from the sun follows one of three pathways: absorption by the atmosphere (25%), reflection back into space (30%), or absorption by the earth's surface (45%). The light absorbed by earth's surface and by the atmosphere is converted from energy in the form of shortwave visible light to energy in the form of longwave infrared radiation (i.e., heat). Several gases in the atmosphere, referred to as "greenhouse gases," absorb some of the heat and reradiate it back toward the surface, increasing surface temperature. Without this naturally occurring greenhouse effect, Earth's average surface temperature would be approximately -18°C , about 33°C colder than it is today.

It should be noted that while the atmospheric greenhouse and actual physical greenhouses both trap heat, they do so via different mechanisms. A physical greenhouse traps air inside the building so that its heat cannot escape by convection; the atmospheric greenhouse absorbs the heat in gas molecules and re-radiates it back toward the earth's surface.

Enhanced Greenhouse Effect

The most important naturally occurring greenhouse gases are water vapor, carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and ozone (O₃). Although water vapor plays the biggest role in generating the natural greenhouse effect, anthropogenic emission of the other gases, along with artificially produced halocarbons, are most important in generating an enhanced greenhouse effect. Detailed instrument data show that concentrations of these gases have been increasing since preindustrial times (1750) (Table 1; Figure 1), particularly in recent decades, largely due to human, industrial, agricultural, and urbanization activities. As the concentrations of greenhouse gases increase in the atmosphere, they continue to trap and re-radiate more heat, resulting in rising surface temperature and other climatic changes.

Increases in CO₂ account for about half of the current direct positive radiative forcing due to anthropogenic emissions (Figure 2). The atmospheric CO₂ concentration has increased by 35% since preindustrial times, as a result of emissions from fossil fuel combustion, land conversion, and cement production, and is continuing to increase by 0.5% per year (Figure 2). If future emissions of CO₂ were maintained at 2005 levels, CO₂'s atmospheric concentration would be roughly double the preindustrial level by the end of twenty-first century. Concentrations of other greenhouse gases, particularly methane and nitrous oxide, also continue to slowly rise. Greenhouse gases tend to remain in the atmosphere for

Table 1 A sample of greenhouse gases affected by human activities

	CO_2	CH_4	N_2O	CFC-12	HFC-134a
Preindustrial concentration	~ 280 ppmv ^a	~ 700 ppbv ^b	~ 270 ppbv	0	0
2005 concentration	379 ppmv	1774 ppbv	319 ppbv	538 ppbv	35 pptv
1998–2005 change	1.9 ppmv y^{-1}	1.6 ppbv y^{-1}	0.7 ppbv y^{-1}	0.6 pptv y^{-1}	3.9 pptv y^{-1}
1998–2005% change	0.5% y^{-1}	0.1% y^{-1}	0.2% y^{-1}	0.1% y^{-1}	23.5% y^{-1}
Atmospheric lifetime ^c (years)	^d	12	114	100	14
Direct radiative forcing ($W\ m^{-2}$)	1.66	0.48	0.16	0.17	0.01

^a CO_2 's concentration ranged from 275–285 ppmv in the preindustrial era (AD 1000–1750).

^b CH_4 's concentration ranged from 400–700 ppbv in the 650,000 years preceding the industrial era.

^cAtmospheric lifetime is the time after emission for the atmospheric concentration of a gas to be reduced by 63% (to 37%, or e^{-1} , of its original concentration); after two lifetimes, the concentration will be reduced by another 63% (to 23%); and so on for three, four, etc., lifetimes.

^d CO_2 does not follow the exponential decay of other gases because it is taken up by multiple sinks. The first lifetime (time to 37%) is about 80 years; subsequent lifetimes are longer. Abbreviations: ppmv, parts per million by volume; ppbv, parts per billion by volume; pptv, parts per trillion by volume.

many years (Table 1) and continue to affect the climate long after initial emissions.

In addition to greenhouse gases, fine particles suspended in the air called aerosols can also affect the climate. Aerosols can be produced by natural sources such as dust and sea spray, and can also be produced by human activities such as incomplete combustion of fossil fuels and biomass. Aerosols can alter the climate by changing atmospheric albedo. These fine particles can both reflect and absorb solar radiation and alter cloud properties to produce a net cooling effect. The overall effect is usually one of cooling, although atmospheric soot over snow or ice can warm regionally. The current estimate of the combined effect of aerosols is $-1.2\ W\ m^{-2}$ compared to $3\ W\ m^{-2}$ due to greenhouse gases (Figure 1). Aerosols are very short-lived in the atmosphere (days to weeks) and respond rapidly to changes in emissions.

Climatic Consequences: Global Warming

Past Climate Change

Scientists use deep ice cores drilled from glaciers in Antarctica, Greenland, and South America to examine ancient climate and atmospheric trends over the last several hundred thousand years. The data from these ice cores reveal a strong correlation between temperature and CO_2 concentrations (Figure 3). The historical swings between Ice Ages and warm periods are triggered by periodic, predictable changes in the tilt of Earth's axis, the direction of its axis relative to the sun, and the shape of its orbit. The initial trigger created by these changes produces biological feedbacks that will be discussed in the Section, Feedbacks. These feedbacks change the amount of CO_2 in the atmosphere, and the resulting greenhouse effect amplifies the initial warming or cooling.

Figure 2 Estimates of the globally and annually averaged radiative forcing due to anthropogenic changes in concentrations of greenhouse gases and aerosols and natural changes in solar output from preindustrial times to 2005. The length of the rectangular bars indicates a midrange estimate of forcing, and the error bars show an estimate of the uncertainty range. The level of scientific understanding is rated by the IPCC as “high” for the long-lived greenhouse gases, “med” for ozone, “med–low” for surface albedo and aerosol direct effect, and “low” for stratospheric water vapor, aerosol cloud albedo effect, linear contrails, and solar irradiance. Reprinted from FAQ 2.1, Figure 2 in Forster PM, Ramaswamy V, Artaxo P, *et al.* (2007) Changes in atmospheric constituents and in radiative forcing. Recent Climate Change

Observational data provides clear evidence of human-induced global warming. Global average surface temperature trends reveal a 0.7°C temperature increase during the past hundred years, with the 10 hottest years on record between 1880 and 2010 occurring between 1998 and 2010.

How do the recent temperature increases compare to natural climate variability? The key drivers of natural climate variability are orbital patterns, solar cycles, and volcanic eruptions. The first two are predictable and are included in climate model projections. Volcanic eruptions are included in retrospective models. **Figure 4** illustrates the amount of temperature change attributable to natural variation (in blue) relative to the total change observed (black line) and the total change predicted (in pink). This diagram illustrates that most of the change experienced during the past century is attributable to human activity and also shows that models can do a good job of replicating past climate system behavior. This ability of models to faithfully reproduce the past provides evidence that they have some predictive power for the future.

Future Climate Change

What will the future bring? Future climate will depend in part on societal decisions about future emissions and in part on emissions that we have already generated. The climate system includes two important time lags. First, long-lived emissions like CO_2 stay in the atmosphere for decades or centuries after the initial release. Second, Earth's heat builds up gradually over many years, creating a slow rise in Earth's temperature. These two factors explain why the emissions produced today commit the planet to a warming trajectory that extends decades into the future.

General circulation models (GCMs) integrate the physics of radiative forcing, ocean dynamics, and other complex Earth-atmosphere processes in order to simulate and predict the climate trends. **Figure 5** illustrates the global

average temperature trajectory for the period 1900–2100 under several different scenarios for anthropogenic emissions. The orange line illustrates the slight temperature increase that would result if atmospheric concentrations were held constant (i.e., emissions were dramatically reduced to a replacement-rate level). The other lines illustrate scenarios with higher levels of emissions. Note that the graph shows only the global average, but temperature change is greater at the poles.

As of 2010, society is on a path that is in line with the upper emissions scenarios. Temperatures are projected to rise by approximately 1.5°C versus preindustrial by 2030 and by 2°C versus preindustrial by 2050. The threshold for “dangerous anthropogenic interference” (DAI) is considered to be 2°C . This threshold has international political significance: the Kyoto Protocol (1997), the Copenhagen Accord (2009), and the Cancun Agreements (2010) are agreements by national governments to take the necessary steps to avoid crossing the threshold of DAI.

The impacts of climate change include effects on agricultural productivity, availability of freshwater, spread of disease, extreme weather events, alteration of ecosystems, and loss of biodiversity (*see* Climate Change and Biodiversity). Climate models point to many climatic impacts of increases in greenhouse gases and aerosols that will be of particular importance to ecosystems and biodiversity. First, surface warming will not be uniform, with greater warming at the poles than at the equator. Winter temperatures are expected to increase more than summer temperatures, and night-time more than daytime temperatures. The incidence of record-breaking hot days will tend to increase in the summer, and fewer frost days are likely to occur in the winter. Second, patterns of precipitation and soil moisture will change. Warming is predicted to increase evaporation and global mean precipitation, and may increase cloud cover. Geographic distribution of precipitation is expected to shift in patterns that are not yet predictable. High and middle latitudes and elevations will experience more winter precipitation falling as rain, earlier

Figure 4 Surface temperature changes caused by natural earth system changes (solar and volcanic activity) (blue) versus temperature changes caused by the combination of anthropogenic and natural changes (pink) versus observed temperature changes (black line). Bands represent 5–95% confidence intervals. Results are taken from five climate models for natural forcings and 14 climate models for combined forcings. Observations are decadal averages. Reprinted from Figure SPM.4 in IPCC (2007) Summary for Policymakers. In: Solomon S, Qin D, Manning M, et al. (eds.) *Climate Change: The Physical Science Basis. Figure 5 Projections for global surface temperature under a wide range of possible twenty-first century emission scenarios. Shading on graph indicates $\pm$ one standard deviation from individual model results. Bars on the right indicate the likely (66% confidence) range of year 2100 outcomes based on the same models used in the graph, plus independent models and observational constraints. Reprinted from Figure SPM.5 in IPCC (2007) Summary for Policymakers. In: Solomon S, Qin D, Manning M, *et al.* (eds.) *Climate Change: The Physical Science Basis. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*. Cambridge, UK and New York, NY, USA: Cambridge University Press.

snowmelt, and reductions of summer soil moisture in non-coastal areas. Third, the frequency and intensity of extreme weather and disturbance events (e.g., drought, deluge, summer heat waves, hurricanes, and fires) are expected to increase. Fourth, average sea level is expected to rise 0.2–2.0 m during this century from a combination of thermal expansion, glacier melt, and ice sheet melt.

Some of these trends have already been observed. For example, more warming has occurred near the poles ($2\times$ versus the global average), hot days and heat waves have become more frequent, cold days have become less frequent, droughts have increased in length and intensity, snowpack is decreasing and snowmelt is occurring earlier at high latitudes and elevations, glaciers are retreating, and sea levels are rising (sea level rose ~ 17 cm during the twentieth century, mostly attributable to anthropogenic climate change).

While some climate changes follow a smooth, predictable trajectory (e.g., global average temperature), other changes are more abrupt. Tipping points occur when a major shift in a tipping element results from a small incremental change in the climate. Examples of potential tipping elements include loss of Arctic summer (September) sea ice, a shift in the monsoons (India, Sahara/Sahel, West Africa) or El Niño patterns, a shift in the Atlantic Ocean circulation, loss of the Greenland or West Antarctic ice sheets, or loss of the Amazon rainforest (due to precipitation shifts). Any one of these changes would have large-scale effects on the rest of the climate system *via* feedback loops (discussed below) and on biodiversity. While scientists have some broad estimates of the temperatures at which these tipping points could occur, the exact tipping points and associated time lags are highly uncertain.

Feedbacks

Climate change can trigger a variety of responses to biotic and abiotic processes, which results in changes in the flow of energy and greenhouse gases between the surface and the atmosphere. As a result of these responses, climate change resulting directly from anthropogenic emissions of greenhouse gases triggers further climate change. These feedbacks are reviewed below.

Geophysical Feedbacks

General circulation models include not only mechanisms underlying direct greenhouse gas and aerosol radiative forcing, but also mechanisms underlying the three large geophysical feedback processes: water vapor, snow/ice albedo, and cloud cover. Because the capacity of the atmosphere to hold water vapor increases as it warms and water vapor acts as a greenhouse gas to further increase temperature, a positive feedback to the climate is created that amplifies warming. The snow/ice albedo effect is also a positive feedback – as warmer temperatures melt highly reflective snow and ice at the poles and high elevations, thus lowering surface albedo, Earth absorbs more sunlight, which augments warming.

Cloud formation adds much of the uncertainty to GCM estimates. If clouds form over highly reflective surfaces (e.g., ice and snow), they reduce the planet's albedo. If they form over low-reflective surfaces (e.g., oceans and forests), they increase the planet's albedo. In addition to uncertainty over where clouds will form, their longevity (before raining out),

height, and shape are also highly uncertain. In short, it is unclear whether there will be more clouds and if so, whether they will have characteristics that create warming or cooling. Currently, model estimates of the cloud feedback effect range from a slight negative feedback to a large positive feedback.

Biogeochemical Feedbacks

Biogeochemical feedbacks are those in which the ecosystem responses to climate changes influence the atmospheric concentrations of greenhouse gases and aerosols or the planet's albedo, which in turn influence the climate. Examples of these feedbacks include: higher rates of decay of organic matter at higher temperatures (increases CO_2), release of methane from melting permafrost (increases CH_4), northward shift of shrubs and boreal forest due to amenable growing conditions (reduces albedo), and increased dust storms due to droughts (increase dust aerosols). Over the past few years, GCMs have been expanded to incorporate many biogeochemical feedback effects and their overall effect is to increase the rate of warming (a positive feedback effect). Many biogeochemical feedbacks due to climate change also interact with other anthropogenic stresses, such as deforestation and pollution, to further influence climate change effects at local, regional, and global scales.

Marine Feedbacks

Climate change is likely to drive many complex marine-based feedback processes, of which only a few are mentioned here. With regard to geochemistry, warm water holds less dissolved CO_2 than cooler water; thus the warming of ocean surface waters expected under climate change will result in a positive feedback since a warmer ocean will release CO_2 to the atmosphere. Because oceans hold approximately 50 times as much carbon in the form of dissolved CO_2 and bicarbonate (HCO_3^-) as there is CO_2 in the atmosphere, this effect could add 1° or 2° C to the predicted equilibrium warming. If the additional surface water warmth travels down the water column, methane could be released from temperature- and pressure-sensitive hydrates that are present in some ocean floor sediments. This would also result in a positive feedback since the released methane, a greenhouse gas, would cause more warming.

With regard to biology, more than a third of annual global primary production occurs in ocean surface waters, primarily by microscopic single-celled organisms called phytoplankton, which form the base of the oceanic food web. Through the process of photosynthesis, CO_2 is fixed by the phytoplankton and thus transferred from the atmosphere to ocean surface waters. Some of this fixed carbon, in the form of dead bodies and fecal matter of phytoplankton and other organisms, sinks into deep ocean layers and sediments and is sequestered there, where it can no longer be exchanged with the atmosphere on short timescales. This process is referred to as the "biological carbon pump" and has been important in maintaining a level of CO_2 in the atmosphere that is currently about 40% lower than it would be in the absence of marine organisms.

Terrestrial Feedbacks

Three to five times as much carbon is stored in terrestrial vegetation and soils than is stored in the atmosphere. Through photosynthesis and respiration, more than one-eighth of atmospheric CO_2 is exchanged each year with terrestrial ecosystems. Changes to terrestrial-atmospheric carbon cycling thus have the potential to produce significant feedbacks to climate change. The feedback pathways for carbon in terrestrial ecosystems are complex, representing both positive and negative feedbacks. Perhaps the most well-known potential carbon cycle feedback is the " CO_2 fertilization effect," which refers to the stimulation of photosynthesis by increased levels of CO_2 , which in turn can result in increased plant growth and greater storage of carbon in vegetation. This effect is limited to situations in which water and other nutrients are available in sufficient supply so that CO_2 is the limiting growth factor.

Climatic changes that will accompany higher concentrations of CO_2 make it even more complicated to predict the net effect of climate change on the storage of carbon in vegetation and soil versus the atmosphere. For example, under climate change, changes in water availability and temperature will reduce the CO_2 uptake and growth of some plants while favoring others. Resulting changes in plant community composition can alter the quantity and quality of litter that enters the soil, which can lead to changes in soil carbon storage. Soil microorganisms will not only respond to changes in litter inputs, but will also be directly affected by changes in climate. Microbes and fungi tend to respire more CO_2 to the atmosphere as temperatures increase. However, rates of respiration depend on levels of soil moisture, and different extremes of water availability (both too much and too little) will tend to decrease respiration. The effects of climate change on microorganisms will also alter fluxes of other greenhouse gases such as methane in wetlands (e.g., northern peatlands, which store large amounts of carbon and may be a source of strong positive feedback to warming) and nitrous oxide in moist tropical soils.

In addition to the more direct effects of changes in temperature and moisture on the terrestrial carbon cycle, indirect effects such as the alteration of fire regimes due to climate change may produce significant feedbacks. In general, predicted increases in fire frequency for many ecosystems as a result of climate change will result in reductions of terrestrial carbon storage, a positive feedback. Those same fires, however, will in many cases increase albedo (by reducing dark forest), a negative feedback. The net effect of fire can be a positive or negative feedback in different locations, and can change over time as the plant community composition changes postfire.

Another set of climate change feedbacks related to changes in albedo may result from climate-induced shifts in land cover and vegetation. The drying of soils and increased desertification expected from climate change will add dust to the atmosphere, like anthropogenic aerosols, that can reduce warming through increases in atmospheric albedo. Surface albedo is also expected to change as the boundaries of biomes shift, since different vegetation types can have different reflectivity. For example, the predicted northward expansion of boreal forest into tundra could decrease surface albedo, resulting in increased surface warming. This mechanism may have acted as a strong positive feedback 6000 years ago when

an initial warming at high latitudes as a result of orbital variations appears to have doubled in magnitude owing to changes in surface albedo from boreal forest expansion.

Climate Change and Biodiversity

Introduction

Currently, the largest reductions in biodiversity result from massive deforestation in the tropics, in conjunction with other sources of worldwide habitat destruction. Even as the razing of vast tracts of tropical forests is expected to lead to immediate direct losses of hundreds to many thousands of species per year, the carbon that is released to the atmosphere through deforestation is amplifying the anthropogenic greenhouse effect. Climate change could lead to losses in biodiversity over the next several hundred years that are similar to or greater in magnitude than losses from direct habitat destruction. Dramatic changes in global climate have the potential to disrupt every ecosystem on Earth, leading to a pervasive trend of biodiversity loss due to climate-related habitat alteration, reorganization, and destruction.

Why does anthropogenic climate change present such a threat to biodiversity? There are two main reasons. First, the rate and magnitude of climate change expected over the next several decades to centuries are greater than any changes that current organisms have experienced. Over the last 18,000 years, starting during the last full glacial period and continuing through the current interglacial period that began about 10,000 years ago, average global surface temperature has gradually increased by about $5 \pm 1^\circ\text{C}$. If we assume conservatively that climate change will increase mean temperature by 5°C over the next 200 years, this represents a 90-fold increase over the recent natural rate of change. In terms of magnitude, a 3°C increase would result in the warmest world in 100,000 years, and a 4°C increase would result in the warmest world in 40 million or more years. Second, climate change will interact synergistically with other anthropogenic stresses such as habitat destruction, pollution, ozone depletion, and alien species introduction to reduce biodiversity by more than just the sum of losses that would occur if each factor occurred independently.

Scientists' ability to specifically predict how biodiversity will be affected by climate change is constrained by large uncertainties associated with local and regional climate change predictions. Much of the following discussion is based not so much on how scientists specifically think biodiversity will change under climate change, but on generic ways in which biota will be affected by climate change that can lead to changes in biodiversity. The term "biota" is used as shorthand to refer collectively to individual organisms, groups of the same types of organisms (populations, species, functional types), and ecological complexes of multiple populations and species (communities, ecosystems). This section summarizes how scientists study the effects of climate change on biota, the types of responses biota can have to climate change, the kinds of biota likely to be harmed by and to benefit from climate change, and evidence for biotic responses to current anthropogenic climate change.

How Scientists Study the Effects of Climate Change on Biota

Species Distribution Models

Climate-vegetation classification systems are types of static models that are based on the hypothesis that climate patterns are the primary determinant of the broad-scale distribution of vegetation types. In 1947, Holdridge developed a "life-zone" concept that used three variables based on temperature and precipitation to predict under what climates, 20 vegetation types should occur. Later researchers refined and added detail to this basic concept by using a wider variety of species and bioclimatic variables that explicitly incorporate drought stress and seasonality (Table 2). These types of static models, referred to as "climate envelope models" can be used for single species or for life zones. They are constructed from comparisons of the current locations of species of vegetation or animals and climate and can then be used in conjunction with maps of simulated future climate to predict shifts in distribution of species due to climate change. The Holdridge life-zone classification has been used to predict the conversion of much of today's boreal forest into temperate deciduous forest. While climate envelope models provide a way to look at the potential global-scale shifts in the distribution of plants or animals under climate change, they are limited in their applicability by a number of factors.

- Novel climates, consisting of combinations of, say, temperature and rainfall that are not found in today's climate, may arise in the future.
- Nonclimatic factors, such as soil type, can limit the ability of vegetation to track shifting climate.
- Species interactions, such as those between plants and pollinators, are often critical to the ability of species to survive; if a plant but not its pollinators can disperse to a new geographic location with suitable climate, it will not be able to establish there.
- Climate envelopes are often constructed from locations of adult plants but the climate conditions may be limiting germination or seedling survival, not adult plants.
- Climate envelopes generally assume that all individuals in a species share the same preferences for climate, whereas populations within a species found across a range of climates may be adapted to local climate.

Table 2 Bioclimatic variables used by Box to predict distribution limits of plant types

$T_{\max}$	Mean temperature of the warmest month ($^\circ\text{C}$)
$T_{\min}$	Mean temperature of the coldest month ($^\circ\text{C}$)
D_T	Range between $T_{\max}$ and $T_{\min}$ ($^\circ\text{C}$)
P	Mean total annual precipitation (mm)
$P_{\max}$	Mean total precipitation of the wettest month (mm)
$P_{\min}$	Mean total precipitation of the driest month (mm)
$P_{T\max}$	Mean total precipitation of the warmest month (mm)
MI	Moisture index: the ratio of P to annual potential evapotranspiration

Source: From 1981, *Macroclimate and Plant Form*, The Hague: Junk Publishers.

- Species face many threats besides climate change, including habitat destruction, pollution such as acid rain, invasion of exotic species, and hunting or fishing pressure, and these threats can act synergistically with climate.

Simulation models, the other major modeling approach, incorporate and link multiple factors such as life-history traits, physiological constraints, biotic interactions, resource availability, and climate in order to predict dynamic changes in biota over the course of time. By using characteristics of individuals, populations, species, or functional types in conjunction with predicted changes in climate, modelers can simulate continuous vegetation responses to climate change at scales that vary from changes within a stand of plants to changes at landscape, regional, and global levels. Vegetation models can be used in turn to look at the changes in habitat and dynamics of other types of organisms. Simulation models not only attempt to predict patterns of change, but also provide means to explore how and why such change might occur. However, these analyses are often constrained by data requirements. Detailed and accurate information may not be available about the biota and environment of interest, and as simulations are scaled up to look at global impacts, specificity is lost. No matter how well models appear to fit observed dynamics, some factors not included in the model may be important for future dynamics, or the model may fit observed dynamics for the wrong reasons, rendering model predictions inaccurate.

Paleobiology

Paleobiologists combine historical climate and biological data to reconstruct past relationships between changes in climate and species distributions. Paleobiological data sources range from ice and soil cores to plant and animal fossils to tree rings and slow-growing corals. Such studies reveal the long-term and integrated direct and indirect effects of past climatic and atmospheric change on past biota and thus facilitate projections about how present-day biota might respond in the long term to anthropogenic climate change. Many crucial insights about previous and potential effects of climate change have emerged from this type of work (*see Impacts of Climate Change on Biota*). However, the generality of these types of studies is limited by the lack of good fossil records for many organisms and strict climatic parallels in the past to both the rate and magnitude of anthropogenic climate change, and by differences in the biology and geology of ancient times compared to the present. In addition, the interactions of climate change with other anthropogenic stresses such as pollution, development, agriculture, and deforestation are novel and not represented in the paleorecord.

Natural Climate Variability

Whereas paleobiologists look to the ancient past for insight into the future, many field biologists interested in climate change look to the present to examine how biota are regulated by and respond to natural climate variability of a magnitude similar to that expected from climate change. Two approaches are used in this type of research. First, scientists

can conduct “space-for-time” analyses along elevational or latitudinal gradients. This approach suggests that the effects of climate change over time on particular biota may be represented by current differences between the biota of interest and the same type of biota found at warmer, lower elevations or latitudes. Second, researchers who conduct multiyear studies at particular sites can monitor the response of biota to the natural interannual variability of climate. In particular, biotic responses to climate in more “normal” years can be compared to biotic responses to very warm years, droughts, early snowmelts, and other climatic events that fit predicted changes due to climate change. In some cases, researchers have access to records of climate and biota from several decades ago and can compare them to current records for the same sites.

This type of research has the advantage of actually studying current biota in the field in relation to climate, but it also has several disadvantages. For example, from one year to the next and from one place to another, sites vary not only in their climate but also in many other factors (e.g., land use history, species composition, topography), making it difficult to establish whether particular climate factors and other nonclimatic factors underlie observed patterns. Even if sites appear to differ primarily in climate, they may differ by predicted amounts of temperature but not by predicted changes in precipitation and soil moisture. Additionally, biota have had longer time periods to adjust and adapt to current climate variation at particular sites than they will have to adjust to different climate changes. Finally, this approach is unable to explore the effects of increased atmospheric CO₂, with the exception of some research on natural CO₂ gradients near hot springs.

Manipulations

Manipulations are one of scientists’ most potent research tools. By conducting controlled manipulation of various climate, atmosphere, and resource conditions expected to change as a result of climate change, researchers can work toward understanding the role of single or multiple factors and their interactions in changing ecosystem structure and function. This type of research is used to predict both how specific anthropogenic climate change scenarios might impact biota and how resulting ecosystem changes may produce feedbacks to the climate system. In climate change ecology, manipulative research falls into two types of approaches: microcosm experiments and field experiments. Microcosms, which generally take the form of laboratory growth chambers of various sizes, can be used to carefully manipulate particular climate change factors (e.g., temperature, moisture, light, nutrients, atmospheric composition) and to monitor the response of soils, single or multiple organisms, assembled simple ecosystems, or intact ecosystem cores taken from the field. Field experiments also manipulate factors in order to look at interactions between climate change and biota, but do so in intact ecosystems (*Figure 6*).

The strengths and weaknesses of these two approaches are interrelated. Although it is relatively easy to manipulate, control, and replicate microcosms, field experiments may be confounded by ecosystem variability and complexity. In field experiments, typically only a very few experimental variables

Figure 6 Profile of a heated plot used in a long-term ecosystem warming experiment to investigate the interactions between climate warming and the ecology and biogeochemistry of a subalpine meadow ecosystem at the Rocky Mountain Biological Laboratory in Gothic, Colorado, USA. The heaters increase downward infrared radiation flux ($+22 \text{ W m}^{-2}$) to a degree comparable to that expected under a $2 \times \text{CO}_2$ scenario. Layout of the plots is shown below; even-numbered plots have heaters and odd-numbered plots are control plots that lack heaters. Adapted from Figure 1b, 1c in Harte J and Shaw R (1995) Shifting dominance within a montane vegetation community: Results of a climate-warming experiment. *Science* 267: 876–877.

can be manipulated, controls can be difficult to establish, and adequate replication is often expensive and time-consuming. However, field experiments have the advantage of being conducted in a natural setting at broader scales that may be more useful for drawing conclusions about complex, “real-world” ecosystem dynamics, compared to highly simplified and small-scale microcosm experiments. In both types of experiment, the relatively abrupt, short-term (months to decades) manipulation of climate may not be a good analog of anthropogenic climate change, which is occurring over decades and centuries. In addition, changes to disturbances such as fires and hurricanes may prove to be more important in determining the abundance and distribution of biota in many ecosystems than the usual experimental focus on “average” changes in variables such as temperature, moisture, and CO_2 .

Integrated Research

Given the limitations of each type of research, the most productive strategies for exploring interactions between ecosystems and anthropogenic climate change integrate multiple research approaches. For example, responses of biota to natural climate variation can be compared to responses of the same biota to manipulated climate change to see how responses differ or stay the same over multiple spatial and temporal scales. Results from field experiments and gradient studies often suggest mechanisms that can be more thoroughly tested in microcosm experiments. Gradient, field experiment, and paleobiological data sets can be used to parameterize, calibrate, and validate models of biotic response. In general, the thoughtful integration of approaches can build on the strengths and avoid some of the limitations of each type of research, thus helping scientists to develop

more rigorous hypotheses about climate change impacts and ecosystem feedbacks.

Impacts of Climate Change on Biota

Types of Responses

Adjustment

The first level, short-term response of any organism to changes in its environment is adjustment, also referred to as acclimatization. All organisms have some degree of physiological, life-history, or behavioral plasticity that enables them to live in a variable environment. The degree of plasticity with regard to climatic and atmospheric conditions varies widely among different kinds of organisms. Therefore, some types of organisms will be able to adjust to relatively large changes in climate, whereas others will be unable to adjust to even apparently minor increases in temperature or slight variations in precipitation.

An example of climatic adjustment in animals involves thermoregulation in vertebrates. Endotherms such as mammals have built-in physiological mechanisms to cope with body temperature changes. Ectotherms such as reptiles have behavioral traits that help regulate body temperature. Because of traits such as these, initial increases in environmental temperature should be well within the tolerances of many vertebrates. In plants, the concurrent increase of atmospheric CO₂ with surface temperature may augment the ability of some individuals, populations, and species to adjust to and flourish under anthropogenic climate change. Increases in CO₂, especially for plants with the common C3 photosynthesis pathway (e.g., most trees and shrubs), can result, at least initially, in the CO₂ fertilization effect mentioned above. Enhanced CO₂ concentrations can increase the ability of these types of plants to tolerate water stress, higher temperatures, and lower light. Other kinds of plants, particularly those with the C4 photosynthesis pathway (e.g., many low-latitude and low-elevation grasses), have physiological mechanisms that enable them to withstand warm temperatures and low availability of water. Such mechanisms provide a means of adjustment to drought stress that may be associated with increased temperatures and evaporation.

While most biota will have at least some capacity to withstand, and in some cases benefit from, initial changes in climate, the rapid rate and large magnitude of climate change are likely to quickly surpass their capacity to adjust to new climate conditions within their prewarming habitats. Biota that cannot continue to adjust will have to respond through evolution, migration, or extinction.

Evolution

Theoretically, populations and species could develop new adaptive traits as a result of evolution in response to anthropogenic climate change, thus enhancing the long-term survival of current taxa under new climate conditions. However, scientists generally agree that evolutionary responses to climate change are unlikely for most taxa since climate is changing rapidly compared to usual rates of evolutionary change. This view is supported by fossil data that reveal the morphological

stasis of many taxa during previous periods of rapid climate change.

In the face of strong selectional pressure there is evidence that some species, especially those with fast generation times, can evolve very rapidly. For example, grass populations grown on soils polluted by heavy metals have shown signs of significant, genetic-based, heavy-metal tolerance within one or two decades. Some insects can evolve increased resistance to pesticides over the course of a few years. These types of responses depend on the presence of appropriate genetic variability in populations and species relative to a strong selective factor. As a result of climate change, populations and species will be exposed to novel environments resulting from climate change and associated shifts in ecosystem structure and function. Since many populations and species have climate-related genetic variability (e.g., differences in high temperature tolerance, drought tolerance), rapid evolution is possible.

Will anthropogenic climate change actually result in directed selectional pressures that are strong enough to drive microevolutionary responses? For at least the next several hundred years, species distributions are likely to be in fairly constant flux, which will tend to disrupt any potentially adaptive trends. Also, rapid evolutionary responses to anthropogenic climate change are unlikely in populations and species that have relatively long generation times, such as trees and many vertebrates. An added constraint on potential microevolutionary responses to climate change is the ongoing reduction in population size and thus genetic diversity of many species as a result of habitat destruction and other stresses. For most biota, other types of responses are far more likely to occur than evolution.

Migration

As current habitat becomes inhospitable owing to direct and indirect effects of climate change, biota will tend to track shifting climate and suitable habitat through dispersal and migration. Consequently, as a result of climate change, organisms are predicted to move generally poleward in latitude and upward in elevation. A rule of thumb is that a 3 °C change in temperature is approximately equivalent to a move of 250 km of latitude or 500 m of elevation. However, migration will be restricted or made impossible to the extent that there are inherent barriers (e.g., low mobility, slow reproductive rates) or external barriers (e.g., mountain ranges, large lakes) to movement.

Fossil records show that for many types of organisms, warming during the last deglaciation induced significant changes in latitude and elevation of species' ranges (Figure 7). Those distributional changes sometimes occurred at very rapid rates. For example, peak migration rates for some tree species in North America during the last deglaciation reached 100–500 m per year, probably as a result of haphazard, long-distance transport of seeds by animals, storms, or water. However, even these very fast historic migration rates only translate into 10–50 km per century, whereas anthropogenic climate change will likely require latitudinal shifts of at least 200–300 km over the next century. In some cases, changes in potential range boundaries resulting from climate change due to doubled CO₂ may exceed 1000 km. For example, suitable habitat for beech trees, which currently grow over

Figure 7 Maps of observed (upper row) and simulated (lower row) percentages for spruce tree pollen in eastern North America over the last 18,000 years. The simulated spruce pollen maps are based on the modern response of spruce pollen percentages to July temperature, January temperature, and precipitation as applied to simulated historical climates. Dark shading indicates the highest abundance of spruce. Reprinted from Webb T III (1992) Past changes in vegetation and climate: Lessons for the future. most of the eastern third of the US, could shift almost completely out of the country and into a much smaller area of the Northeastern US and Southeastern Canada as a result of a $2 \times \text{CO}_2$ atmosphere (Figure 8). The rapid pace of anthropogenic climate change will easily outstrip the capacity of some organisms to move or disperse to a suitable new

habitat. In addition, human destruction of habitat will create insurmountable barriers to migration for biota that have difficulty crossing large areas of urban development or agricultural use. In the short run, any migration that does occur may tend to increase local levels of biodiversity in some ecosystems as new species move in before old species completely

migrate or die out. This lag effect will tend to disappear with time.

Extinction

Biota that are unable to adjust, evolve, or migrate are unlikely to survive long in their prewarming habitats. As a result of climate change, organisms may be exposed to increasing physiological stress, abandoned by their mutualists and prey, outcompeted by more flexible neighbors or incoming species, and attacked by new predators and pests. Although micro-evolutionary responses are possible for some populations, rapid genetic adaptation is likely to occur in very few. Many species will be faced with migration problems. Even in species that successfully migrate, some populations are likely to go extinct, particularly at southern and lower edges of species' ranges, reducing genetic variability. Extinctions attributable primarily to climate change will be few over the next several decades, but will increase dramatically as time passes, climate change intensifies, and biotic response options narrow.

Types of Biota Impacted

Organisms at Risk

Given our knowledge of climate change and biology, the kinds of biota most likely to be at risk from climate change over the next several decades and centuries can be characterized. They include organisms that live in particular types of habitats such as at higher latitudes, on mountaintops, in low-lying coastal areas, or on islands. Scientists know with a high degree of certainty that temperature increases due to climate change will be greatest in polar regions. Therefore, higher-latitude temperate and Arctic/Antarctic ecosystems such as boreal forest, tundra, and peat bogs will experience both rapid and severe temperature increases, resulting in profound biotic change and disruption. Temperature increases will also be greater at higher elevations. Montane biota will tend to move up to cooler elevations. Biota already limited to mountaintops will be at serious risk of local extinction due to alteration of summit climate, the lack of potentially suitable habitat to migrate to, and the encroachment of lower-elevation species. Additionally, even small increases in sea level (i.e., several centimeters) due to climate change can result in altered coastal marine dynamics and flooding of low-lying areas. Rising sea levels will destroy or cause severe damage to ecosystems at the terrestrial/marine interface, such as salt marshes, estuaries, mangroves, and sand dunes, and are likely to disrupt coastal marine food webs.

Biota that lack the ability to readily disperse or move will be at a serious disadvantage. These include plants whose seed or clone dispersal rates and animals whose movement rates lag behind rates of climate change; slow-growing populations and species that will not have time to adjust to new conditions; biota that cannot or are slow to cross geographic barriers, for example, fish in isolated lakes, low-elevation plants bounded to the north by mountain ranges, and tropical forest birds and insects that do not cross unforested areas; organisms that depend on other biota for habitat or food, but that have very different degrees of mobility; species such as monarch butterflies and migratory shorebirds that have multiple habitat requirements; and relic biota that have been left

in small, unusual habitats by chance and have no nearby habitat.

Organisms that are sensitive to extreme disturbance events, dependent on particular hydrological regimes, or that have certain kinds of physiological tolerances are also likely to be negatively impacted by climate change. Even though disturbances such as fires and hurricanes are a natural part of ecosystem dynamics, any increases in frequency and intensity of such disturbances due to climate change are likely to disrupt biota. For example, ecosystems such as tropical montane forests may have less time to recover between hurricanes, limiting the development of slow-growing, late-successional species. In terms of hydrological cycles, though it is often uncertain at local and regional scales how and to what degree precipitation and moisture availability will result from climate change, it is quite certain that changes will occur. Such changes could be critical in ecosystems such as tropical forests where the availability of food resources for animals is dependent on the timing of rainfall. In montane areas, many organisms will be very sensitive to changes in the snowpack and snowmelt. Regarding physiological tolerances, some organisms are adapted to living within a narrow range of limits of temperature, moisture, nutrients, light, and atmospheric composition, while others have wider tolerances but are already operating close to a threshold, beyond which their ability to live, grow, and reproduce is severely limited. Climate change may force the environment past physiological limits for some organisms, resulting in severe impacts, especially if dispersal or growth is slow. For example, slight increases (1–2 °C) in surface water temperature can induce bleaching and mortality of coral reefs, which have very slow rates of growth and provide habitat for many marine species.

Populations and species with few numbers, low genetic variability, or limited or unusual ranges will be vulnerable to climate fluctuations and will be at increased risk of extinction. Taxa that have highly specialized relationships with organisms are also at risk. Some species depend entirely on just one or a very few other species for nourishment or reproduction. If species respond very differently to changes in climate than do the species they depend on, and they cannot substitute other organisms to fulfill those roles, they will go extinct. Unusual or unique ecosystems may break apart as populations and species respond in largely individualistic ways to climate change and as feeding and other species interactions are disrupted.

Finally, climate change may negatively impact taxa that are already being challenged by other anthropogenic stresses. Humans engage in many activities that result in deleterious impacts such as habitat destruction, acid deposition, pollution, ozone depletion, and alien species introduction. When organisms are weakened by one of these stresses, they tend to become even more vulnerable to other stresses such as climate change. For example, insect pests can damage vegetation more when pollutants reduce plants' resistance to herbivory and warmer temperatures encourage pest population growth. If those insect pests happen to be alien, they may cause even more damage owing to lack of local predators and because local plants may lack resistance to alien pests. Also, changes in land use such as deforestation can reduce and isolate populations as well as create barriers to migration through habitat fragmentation and destruction.

Organisms Likely to Benefit

Climate change will benefit some biota through increases in abundance and range expansions, often at the expense of more at-risk biota. Types of biota likely to benefit from climate change include those that migrate easily, are opportunistic or generalists, or have high variability and rapid reproduction. Biota that are highly mobile and have rapid dispersal rates, such as some kinds of winged insects, will be equipped to track changing climate. Opportunistic organisms that can colonize disturbed areas will be at an advantage because they will be able to migrate through marginal habitat and establish in climatically disrupted ecosystems. For example, climate change is expected to promote the spread of already weedy introduced plant species, and may facilitate the escape of more garden cultivars into natural ecosystems. Generalist organisms that flourish in a wide variety of environments and have either wide tolerances for variable resource availability and climate or many possible prey items will fare better than highly specialized organisms. Also, populations and species with lots of phenotypic or genetic variation and rapid reproductive rates have the best chances of adjusting and adapting to rapidly changing climate. Finally, some organisms will be favored by new optima that result from climate change. For example, temperature increases are expected to increase parasite and insect development time, allowing parasites to spread with migrating insect hosts and promoting pest infestation and parasite infection of new hosts. These types of responses may lead to range expansions of agricultural pests and disease transmissions, as well as more frequent outbreaks.

Impacts on Communities

A key insight from the fossil record is that species tend to respond to climate change individually rather than as a group. Thus, while the general trend for species is to move poleward and to higher elevations as climate warms, particular species can vary quite dramatically in how fast and how much their ranges contract, expand, or move, what directions they move in, and at what rate they move around or over barriers such as mountain ranges. Consequently, past communities repeatedly disassociated and re-sorted into novel combinations. In some cases, although the same species still exist, there are no modern examples of historic species associations. For example, for several thousand years at the end of the last glacial period, spruce trees grew in open parklands in association with sedges. Today spruce is found in a completely different ecosystem type, the closed-canopy boreal forest, in association with birch, alder, and fir. Anthropogenic climate change is likely to result in the reconstitution of communities and ecosystems in unexpected ways.

Biota tend to move individually in response to long-term climate change because tolerances to climatic and atmospheric conditions are often specific to the organism, population, or species. Individualistic responses can lead to apparently counterintuitive shifts in range, especially if temperature is not the primary determinant of distribution. For example, the distribution of the gopher tortoise during the most recent deglaciation shifted south, rather than north. One hypothesis for this pattern is that seasonal climate extremes increased with warming, and that these extremes were more important for determining tortoise distribution than warming.

In addition to climate and atmosphere, other abiotic factors (e.g., soil type, topography, disturbance regime, site history) and biotic interactions (e.g., mutualism, competition, predation, pollination) can play significant roles in determining the abundance and distribution of biota in both the short and long term. The interplay of all of these factors over time can result in complex and often unpredictable changes in the distribution, abundance, and diversity of biota.

Climate change will also precipitate many asynchronies that reduce the ability of biota to respond effectively to climate change. “Asynchrony” refers to a mismatch in timing or rate of change. One type of asynchrony already discussed is the mismatch between very rapid rates of anthropogenic climate change and slower rates of dispersal and migration for many species. Another type of asynchrony due to climate change is the potential mismatch between required resources and the availability of resources. Organisms are embedded within a network of relationships with other organisms, which they may depend on for sustenance and reproduction. However, different types of organisms may be affected very differently by climate change, which can disrupt biotic relationships that are important for community and ecosystem dynamics. For example, many species of flowering plants depend on specific animal pollinators such as butterflies, hummingbirds, and bees for successful reproduction, and the pollinators depend on those plants for food. In a hypothetical example, if the timing of flowering in a plant is primarily determined by early season temperature, while the emergence and activity of its pollinator is primarily determined by the amount of daylight, the shifting of temperature but not light levels due to climate change could lead to the pollinators being active after the plants flower. This type of asynchrony can reduce the reproduction and abundance of the plants, and reduce the availability of food for the pollinators. If the species involved are highly specialized on each other, they are likely to go extinct. These types of disruptions to species interactions can potentially alter the structure, dynamics, and stability of entire food webs and other ecological networks such as pollination and seed dispersal networks.

Evidence for Current Climate Change Impacts on Biota

During the 1990s, researchers started reporting the first evidence that climate change during the twentieth century has begun to influence populations, species, and ecosystems (see **Box 1** for a bibliography of the sources of information included in this section). Some evidence comes from coastal marine systems. Between 1951 and 1995, zooplankton biomass in coastal southern California waters decreased by 80% over four decades, at the same time the surface water layers warmed more than 1.5 °C in some areas. The surface warming appeared to result in changes to stratification and the thermocline that led to a reduction in upwelling of nutrients and thus primary production by phytoplankton, the ultimate food source of zooplankton. Other research compared changes in abundances of 45 invertebrate species in a central California intertidal community from the 1930s to the 1990s. During that period of time, annual mean shoreline temperature at the study area increased by 0.75 °C, and average summer

temperature increased by 2.2 °C. Eight of nine species with a southern geographic range showed significant increases in abundance, whereas five of eight species with a northern distribution showed significant decreases. Species with wide distributions showed no strong patterns of change.

At high elevations and latitudes, terrestrial vegetation appears to be responding to the warmer climate. A comparison of 40- to 90-year-old records of plant distribution on high-altitude mountaintops (~2900–3500 m) in the Alps to 1992 data, given a 0.7 °C increase in mean annual temperature during that time period, found upward migration rates by nine “typical” species of <1–4 m per decade. In addition, species richness increased over time, with the increase most pronounced at lower-altitude summits. Evidence from satellite data from 1981 to 1991 suggests that the photosynthetic activity of terrestrial vegetation in northern high latitudes increased by 7–14% over that time period. This increase may indicate an intensification of plant growth associated with a 12-day increase in the growing season.

Insect species are also displaying sensitivity to recent climate change. Historical records and the recent status of 151 populations of Edith's checkerspot butterfly throughout its entire range show that the net extinctions of populations were significantly greater at southern latitudes and lower altitudes, resulting in an observed northward and upward shift in the species' range during the last several decades. In a later study that examined range shifts in 35 nonmigratory European butterfly species during the last century, 63% of the species displayed northward range shifts of 35–240 km, while only 3% shifted south.

Vertebrates also appear to be sensitive to recent climate change. Current evidence suggests that birds are both breeding earlier and shifting their ranges northward in response to warming. From 1971 to 1998, the average timing of first clutch in the Mexican jay in Arizona occurred 10 days earlier. This change was associated with significant increases in monthly minimum temperatures. Twenty UK bird species over 25 years displayed long-term trends toward earlier egg laying in most species. A data set of 36 bird species over 57 years suggest that 86% of the species display significant relationships between timing of egg laying and temperature or rainfall. Furthermore, the breeding distributions of British birds over a recent 20-year period indicate that the northern margins of the species' ranges moved north by an average of 19 km.

In general, the observations of most of these types of studies are consistent with predictions of impacts of climate change on biota, and demonstrate how just a small amount of climate change over brief time periods can lead to significant ecological changes.

Conclusions

The enhanced greenhouse effect, in conjunction with other anthropogenic stresses, is likely to precipitate unprecedented changes to Earth's climate and ecosystems. Though the details of how climate change will affect biodiversity are often hard to predict, there is little doubt that biological impacts will be pervasive and often dramatic. Studying the effects of climate change on biota can help in the formulation of strategies for conserving biodiversity and ecosystem structure and function in the face of potentially massive change and loss. Such knowledge is also crucial for refining predictions of the future rate and magnitude of climate change, since biological responses are likely to produce significant feedbacks that can augment or dampen climate change at local, regional, and global scales. Understanding and addressing the interactions between climate change and biodiversity represents one of the greatest challenges that scientists and policymakers face in the twenty-first century.

Glossary

Carbon isotope composition Ratio of common isotopes of carbon (^{12}C and ^{13}C) analyzed in a mass spectrometer and reported in delta notation ($\delta^{13}\text{C}$) relative to a standard (usually Pee Dee belemnite) and reported in parts per thousand (permil), used as a proxy for atmospheric methane abundance.

Chemical index of alteration Molar ratio of alumina over alumina plus soda, potash, lime, and magnesia, determined by whole-rock chemical analysis, and used as a proxy for the residue (alumina) versus solutes (soda, potash, lime, and magnesia) of hydrolytic weathering, used as a proxy for paleoprecipitation.

Methane clathrate Methane (CH_4) gas frozen in ice within deep submarine sedimentary pore space or permafrost.

Oxygen isotopic composition Ratio of common isotopes of oxygen (^{16}O and ^{18}O) analyzed in a mass spectrometer and reported in delta notation ($\delta^{18}\text{O}$) relative to a standard (usually Pee Dee Belemnite) and reported in parts per thousand (permil), used as a proxy for paleotemperature and global ice volume.

Soil Bk horizon Level within a soil of carbonate (calcite or dolomite) enrichment in the form of nodules, mottles, rhizoconcretions, or filaments, used as a proxy for paleoprecipitation.

Soil salinization index Molar ratio of soda and potash over alumina, determined by whole-rock chemical analysis, and used as a proxy for paleotemperature.

Stomatal index Percentage of stomatal openings compared with epidermal cells, used with fossil plant cuticles as a proxy for past atmospheric CO_2 levels.

Introduction

A variety of natural processes appear to have dramatically increased atmospheric greenhouse gases in the geological past: asteroid impact, flood-basalt volcanic eruption, release of submarine or permafrost methane clathrates, and contact metamorphism of coal measures by igneous intrusions (Retallack and Krull, 2006). Abrupt transients of atmospheric CO_2 in the past are discernible from proxies such as the stomatal index of fossil plants (Retallack, 2002) and carbon isotopic composition of pedogenic carbonate (Tabor *et al.*, 2004). Abrupt transients in atmospheric CH_4 are discernible from proxies such as carbon isotopic composition of organic matter (Retallack and Krull, 2006). These indications of atmospheric conditions can be matched with indications of temperature change, such as the oxygen isotopic composition of marine shells (Veizer *et al.*, 2000) and desalinization of soils (Sheldon *et al.*, 2002). Other climatic consequences of CO_2 -induced warming include changes in mean annual precipitation from depth to carbonate (Retallack, 2005a) and degree of base depletion of paleosols (Sheldon *et al.*, 2002). These indications of global change can be compared with past records of life, such as biodiversity (Sepkoski, 1996). Indications are already clear that some past global warmings due to increases in greenhouse gases were hardships for life and detrimental to biodiversity.

Proxies for the Past

A critical difference between evidence from the fossil record and studies of the modern environment is the limitation of

preservation. Measurements such as air temperature measured directly today must be inferred for the geological past from proxy measurements, which are preserved features of rocks or fossils known to vary with temperature. Such proxy measurements depend for their accuracy on the degree to which they are known to covary with temperature today, and the degree to which they have resisted alteration during burial. There are more such proxies than can be adequately discussed in this short account, which is limited to explaining proxies applied to two time series of global warmings in the Cenozoic (Figure 1) and Permian (Figure 2).

Paleotemperature

A popular proxy for global marine paleotemperature is the inverse relationship between temperature and oxygen isotopic value ($\delta^{18}\text{O}$) of carbonate in shells of marine foraminifera (Zachos *et al.*, 2001), mollusks and brachiopods (Veizer *et al.*, 2000). Water vapor with the light isotope (^{16}O) evaporates from a cold ocean more readily than water vapor with the heavy isotope (^{18}O), thus leaving ocean water and bicarbonate used in shell manufacture isotopically heavier (more positive in standard $\delta^{18}\text{O}$ notation permil). This proxy for oceanic paleotemperature is compromised by global ice volumes, which are a separate reservoir dominated by the light isotope (^{16}O). As either a global ice volume or local temperature signal, marine biogenic carbonate oxygen isotopic composition is an important global change indicator (Figure 1b). Disentangling the different signals of ice volume and temperature from oxygen isotope values requires independent proxies for ice volume or temperature, which have their own problems. Another problem is burial recrystallization of fossils,

Figure 1 Cenozoic global change indicators: (a) carbon isotopic composition of benthic foraminifera (Zachos *et al.*, 2001), (b) oxygen isotopic composition of benthic foraminifera (Zachos *et al.*, 2001), (c) mean annual temperature of paleosols in Montana inferred from paleosol salinization index (Sheldon *et al.*, 2002), (d) mean annual precipitation of paleosols in Montana inferred from paleosol chemical index of alteration (Sheldon *et al.*, 2002), (e) mean annual precipitation of paleosols in Utah and Montana inferred from depth to Bk horizon in paleosols (Retallack, 2005b), (f) CO₂ concentration in the atmosphere estimated from the stomatal index of fossil *Ginkgo* leaves (Retallack, 2002). Times of high CO₂ are generally warm and wet.

especially small, porous fossils such as foraminifera. Observations of clam or brachiopod shells in petrographic thin sections or the scanning electron microscope for original biogenic microstructure are sufficient to rule out burial alteration (Veizer *et al.*, 2000).

A proxy for paleotemperature on land is based on observations that warmer climates have greater evapotranspiration than colder climates, and thus leach more alkali cations from soils. The soil salinization index, or molar ratio of potash plus soda to alumina in the clay-enriched subsurface (Bw or Bt) horizons of soils, shows a clear inverse relationship with mean annual temperature in North American soils (Sheldon *et al.*, 2002). Such estimates of paleotemperature from paleosols show trends broadly comparable with marine isotopic records

Figure 2 Permian global change indicators: (a) CO₂ concentration in the atmosphere estimated from the stomatal index of fossil *Lepidopteris* leaves (Retallack, 2005c) and carbon isotopic composition of paleosols (Tabor *et al.*, 2004), (b) carbon isotopic composition of marine limestone from Sovetashan, Armenia (Baud *et al.*, 1989) and of organic carbon from Talcher, India (de Wit *et al.*, 2002), (c) paleotemperature indicated by glendonites and paleosols from the Hunter Valley, New South Wales, Australia (Retallack, 2005c), (d) paleoprecipitation from depth to Bk horizons in paleosols of Oklahoma and Texas, USA (Retallack, 2005c). Times of high CO₂ are generally warm and wet, and some are also times of significant negative carbon isotope excursions.

(Figure 1c). This paleosol proxy for paleotemperature can be compromised by burial alteration of soil clay mineral composition, particularly illitization, which can be assessed by X-ray diffractograms of clay (Retallack, 2001).

Other indications of paleotemperature on land are not so fully quantified, but nevertheless locally useful (Figure 2c). Deeply weathered kaolinitic soils (Ultisols) are not found at mean annual temperatures lower than 12 °C, whereas soils

with ice disruption (Gelisol) are found in regions with mean annual temperature no more than 0 °C. Similarly, ikaite crystals ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) or their pseudomorphs (glendonites) are large spindle-shaped structures within sediment of lake or ocean bottoms, and unstable in waters warmer than 5 °C (Retallack, 2005c).

Paleoprecipitation

The increased depth to carbonate nodules (Bk horizon) in modern soils with increasingly humid climates was first documented eastwards from the Rocky Mountains, USA. This relationship was subsequently shown to be a global phenomenon, and attributed to increases in acidifying soil respiration with rainfall (Retallack, 2005a). Long sequences of paleosols show considerable variation in paleoprecipitation (Figures 1e and 2d). This measure of paleosols is compromised by compaction due to burial, but corrections are applied based on unfolding of formerly planar features or on thickness of overburden. Corrections for different levels of atmospheric carbon dioxide can also be made, but these are not very large (40 mm per annum more rainfall for five times preindustrial level of CO_2), because atmospheric variations in carbon dioxide levels are dwarfed by soil respiration in most soils.

Another proxy for paleoprecipitation is based on observations that wet climate soils are more leached of alkali and alkaline earth cations than dry climate soils. The chemical index of weathering without potash, or molar ratio of alumina, lime, magnesia, and soda to alumina in the clay-enriched subsurface (Bw or Bt) horizons of soils shows a clear relationship with mean annual precipitation in North American soils (Sheldon *et al.*, 2002). This geochemical proxy shows trends comparable with the physical proxy of calcic horizon depth in the same paleosols (Figure 1d). Leaving out potash, a common soil cation, obviates problems with burial illitization (Retallack, 2001). The chief problems with this proxy are local refreshing of soil fertility, for example, by limestone colluvium or volcanic ash, which are best detected through petrographic thin sections of the paleosols.

Atmospheric CO_2 and CH_4

A useful proxy for atmospheric CO_2 is the stomatal index of fossil leaves. This paleobotanical paleobarometer is based on the observation that plant leaves have fewer stomates when atmospheric CO_2 is high than when atmospheric CO_2 is low (Wynn, 2003). Stomatal index is the number of stomatal openings as a percent of epidermal cell numbers, and is preferable to measures of stomatal density, because it is less affected by competing effects of aridity, salinity, and soil nutrient deficiency. A major limitation of this approach is that sensitivity to carbon dioxide is taxon-specific, and few taxa span long periods of geological time. The living fossil *Ginkgo biloba* has been used as a standard for atmospheric CO_2 estimates from congeneric fossils back some 230 My (Retallack, 2002). Other fossils of *Lepidopteris* in the same 230–200 million-year-old deposits as *Ginkgo* fossils have similar stomatal anatomy and index, and can be used to extend atmospheric CO_2 estimates back 300 My (Figures 1f, 2a and 3).

The principal limitation of this approach is its requirement of preserved plant cuticles preparable in sufficient volume to obtain statistically valid stomatal index counts (Retallack, 2002).

Another proxy for atmospheric CO_2 is the carbon isotopic composition of pedogenic carbonate. Plant-respired CO_2 in soil pores has much more light carbon (^{12}C) than heavy carbon (^{13}C) because of the very marked preference of photosynthesis for the light isotope. Animal and microbe-respired CO_2 in soil pores is also isotopically light because the food chain starts with plant material. In contrast, the isotopic composition of CO_2 in the atmosphere is isotopically heavy CO_2 degassed from volcanoes, and the mixing of these two end-members is a function of atmospheric CO_2 partial pressures. The approach is compromised by effects of soil temperature and productivity, which can in part be compensated by geochemical and petrographic study of paleosols (Tabor *et al.*, 2004). A more serious limitation is temporal variation in isotopic composition of the atmosphere, which can be approximated from analysis of organic matter of the same age as the soil carbonate (Retallack, 2002). This requires large samples because carbonate nodular soils of dry climates are lean for organic matter. This is a potentially voluminous source of past atmospheric CO_2 estimates, because calcareous paleosols are common (Figure 2a and d).

A proxy for atmospheric CH_4 is the carbon isotopic composition of organic matter, such as fossil leaves, wood, humus, or dispersed organic matter. The carbon isotopic values of methane reflect an unusual dominance of ^{12}C over ^{13}C . Whereas most organic matter ranges from -22‰ to -30‰ $\delta^{13}\text{C}$, thermogenic CH_4 is -35‰ to -55‰ , typically -40‰ , and biogenic CH_4 is -35‰ to -120‰ , typically -60‰ (Clayton, 1998). These measurable differences are preserved in plants because atmospheric CH_4 oxidizes within about a decade to isotopically unusual CO_2 , which is then used for photosynthesis, and buried with the death of the plant. The carbon isotopic anomaly at the Permian–Triassic boundary is so profound in both marine and nonmarine rocks worldwide (Figure 2b) that release to the atmosphere of some 2000 Gt of methane are required (Berner, 2002). This is an enormous atmospheric injection of a mass of methane equivalent to the carbon in all current terrestrial biomass and soil carbon (1 Gt is 10^{15} g). A limitation with this proxy is that the amount of methane can only be calculated if an original isotopic composition is assumed: Berner's estimate was calculated for biogenic values of -60‰ , and is low compared with estimates assuming thermogenic values of -40‰ . Sources of such large amounts of methane include outburst from submarine methane clathrates and thermal alteration of coals by volcanic intrusions (Retallack and Krull, 2006).

Biodiversity

Past biodiversity is estimated from the numbers of families, genera, or species of fossils within particular geological periods or stages. For truly global coverage such estimates come from literature compilations, for example the *Treatise of Invertebrate Paleontology*, and now increasingly from computer databases. The most robust of these is the record of skeletonized marine invertebrates (Sepkoski, 1996), but estimates

of plant and vertebrate diversity are also available (Benton, 1995). Such proxies of biodiversity suffer from fundamental limitations of preservational bias and study bias. They are clearly an underestimate of past diversity because many weakly skeletonized and soft-bodied creatures are preserved only in rare amber or black shales. There is also a clear bias between groups, with trilobites, for example, attracting more taxonomic attention than corals. Some periods of time are better represented by rocks than others, because of changes in sea level, and so have inflated diversity compared with less well-represented times.

Correlation Between Biodiversity and Global Warming

Many data on paleotemperature and paleoprecipitation are now available, and no clear relationship emerges between them and biodiversity. This is to be expected because climate is so heterogeneous around the world that climate change may induce diversity loss in one part of the world but diversity gains elsewhere. An exception is atmospheric CO₂ levels and marine generic extinction (Figure 3), which shows positive correlation (Figure 4). With 42 degrees of freedom and a *t* value of 6.7, this relationship is highly significant ($p < 0.0001$).

The relationship between CO₂–CH₄ greenhouse and extinction is best understood in extreme cases, such as the End-Permian mass extinction, widely acknowledged to be the greatest life crisis in Earth history (Sepkoski, 1996). An abrupt increase in atmospheric CO₂ is indicated at 250 Ma by stomatal index decline of seed ferns (Figure 2a), and contemporaneous transient CH₄ outburst is indicated by markedly lower carbon isotopic composition of organic matter and marine carbonate worldwide (Figure 2b). Modeling of this atmospheric pollution event with reducing gases may have resulted in geologically rapid (over some 20,000 years) draw-down of atmospheric O₂ from levels of 35%, which is higher than present levels of 21%, to levels as little as 12% (Berner, 2002). Such an atmospheric redox crisis has suggested several mechanisms of extinction for different kinds of organisms.

In the sea, the most lethal effect would have been excess CO₂ (hypercapnia) and low O₂ (hypoxia). This would adversely affect skeletonized organisms with limited ventilatory capacity such as corals and brachiopods, which were mostly extinct, rather than more muscular bivalves and ammonoids, which survived in great numbers but limited diversity. Corals may also have been affected by postapocalyptic global warming, inducing expulsion of zooxanthellae and coral bleaching. No coral reefs are known for the first 6 My of the Triassic, a conspicuous “reef gap” in the fossil record of coral reefs extending back to the Ordovician.

Among land plants, the most lethal effect would be low O₂ (hypoxia) in soil solution, endangering root respiration, especially in swampy soils already challenged for aeration by waterlogging. This would adversely affect swamp plants such as glossopterids and lycopsids, which became extinct, with less-severe effects on surviving horsetails, true ferns, seed ferns, and conifers. No peat swamps are known for the first 6 My of the Triassic, as indicated by a “coal gap,” which is the most profound break in the record of coals since their first appearance in Devonian rocks.

Figure 3 (a) Records of atmospheric CO₂ at geological stage boundaries from stomatal index of *Ginkgo* and *Lepidopteris* and (b) of percentage generic extinction at those same geological stage boundaries from compilations of shelly marine invertebrate taxonomy for the past 300 My.

Figure 4 Cross-correlation between CO₂ and extinction levels at geological stage boundaries shown in Figure 3.

Among land vertebrates, atmospheric O₂ depletion (hypoxia) would have resulted in conditions at sea level more like those found at high altitude today, leading to death by pulmonary edema. Surviving vertebrates were primarily small burrowing species, preadapted to poorly ventilated spaces, and with bony palate, large chests, and short limbs common in high-altitude vertebrates today (Retallack and Krull, 2006).

The Permian–Triassic boundary crisis was extreme, a global warming and atmospheric redox perturbation of unusual magnitude. Other comparable events of lesser magnitude (Figures 1–3) had less-severe effects on biodiversity (Figure 4). A base level of about 10% generic extinction at very low levels of atmospheric CO₂ reflects typical differences in biota from one geological stage to another, and may be an artifact of

long spans of geological time used to calculate extinction rates. Nevertheless, background rates of biodiversity loss grade insensibly into global mass extinctions.

Environmental Consequences of Past Global Warming

The 18 events of global greenhouse in the past 300 My (Figure 3) give a new perspective on the current anthropogenic greenhouse. Instead of a unique event, current global warming can be considered among an array of earlier global warming events showing a spectrum of severity. Consistent environmental correlates of global warming can now be observed in multiple examples. Past global warmings furnish a variety of environmental expectations for global warmings of the future.

Soil Acidification

Increased atmospheric CO_2 creates greater volumes of carbonic acid (H_2CO_3), which is the chief proton source for hydrolytic weathering. Atmospheric acidity is minor compared with the effect of soil respiration, which can raise soil CO_2 levels to 100 times that of the atmosphere and generate large volumes of carbonic acid. Furthermore, increases in rainfall (Figure 1d, e, and 2d) and temperature (Figures 1c, and 2c) with higher atmospheric CO_2 levels raise both primary and secondary productivity of soils, and thus soil respiration. Thus, a variety of related effects accelerate chemical weathering at times of high atmospheric CO_2 , more rapidly depleting soils of alkaline soil nutrient cations such as Ca^{2+} , Mg^{2+} , K^+ , and Na^+ . The result is the spread of base-poor kaolinitic soils (Ultisols and Oxisols) and soil-weathering products (bauxites) to high paleolatitudes at times of CO_2 greenhouses (Retallack, 2001).

Marine Alkalinization

Increased chemical weathering at times of high CO_2 has the effect of adding more soluble ions to groundwater and ultimately the sea. The ocean is thus buffered with bases, mainly bicarbonate (HCO_3^-), which is the conjugate base to carbonic acid. Also enhanced in groundwater and the ocean are basic cations (Ca^{2+} , Mg^{2+} , K^+ , and Na^+), which are important biological nutrients. Moderate levels of oceanic fertilization would have promoted coral and shellfish growth, and thus limestone formation. High levels of fertilization promote seafloor anoxia, and pyritic black shale formation, commonly seen at times of global warming. Extreme alkalinization may explain abiotic precipitation of seafloor fans of calcite (Knoll *et al.*, 1996).

More Humid Climate

Global warming induced by CO_2 increases the water vapor holding capacity of the atmosphere. Water vapor itself is a powerful greenhouse gas, thus amplifying CO_2 -induced warming. Unlike CO_2 , however, water is regularly rained out of atmosphere and so is not a primary control of greenhouse warming. Thus, it is not surprising to find evidence from both

chemical weathering and depth of calcic horizons in paleosols that times of high CO_2 were also times of greater mean annual precipitation (Figure 1d, e, and 2d).

Enhanced Climatic Seasonality

Tropical monsoonal climates have very pronounced dry seasons interspersed with short deluges of rain, and soils of such climate have a distinctive spread of pedogenic nodules throughout the soil profile. Less seasonal climates in contrast have carbonate nodules within well-defined (Bk) horizons. Thickness of soil with nodules is a proxy for the difference between the mean precipitation of the driest and wettest month, and seasonality of precipitation as well as mean annual precipitation both increase during atmospheric CO_2 spikes (Retallack, 2005a).

Increased Runoff

Increased rainfall at times of atmospheric CO_2 spikes would be expected to result in increased stream runoff, with the complication that increased rainfall also appears to increase plant productivity and stature and thus soil moisture retention. In the extreme case of the Permian–Triassic boundary, increased runoff in a postapocalyptic greenhouse of the earliest Triassic is apparent from a change in stream architecture from meandering to braided, and appearance of beds of eroded soil clods (Retallack, 2005b). Such changes are not so obvious in lesser atmospheric CO_2 spikes, such as the middle Miocene warm-wet spike in Montana (Figure 1c–e).

Rising Sea Level

Shrinking ice caps and thermal expansion of the ocean leads to marine transgressions at times of high atmospheric CO_2 . The record of sea level change through time supports this deduction (Haq and Al-Qahtani, 2005). Especially striking are expansions of large epicontinental seaways on stable continental platforms. In Utah, for example, most Mesozoic rocks are nonmarine, but these red eolian, fluvial, and pedogenic red beds include thin marine limestones: Sinbad Limestone (Smithian, 249 Ma), Virgin Limestone (Spathian, 247 Ma), Carmel Formation (Callovian, 164 Ma), and Tropic formation (Cenomanian, 94 Ma). These were all times of high atmospheric CO_2 (Figure 3).

Shrinking Cryosphere

Global warming results in melting of polar and alpine ice caps and glaciers, and surrounding regions of periglacial soils. In accord with this view, glacial tillites, varved shales, and dropped pebbles are limited in temporal distribution to well-defined “Ice Ages.” The ice age of the past 1.6 My is presaged by high-latitude ice-rafted debris as old as 30 Ma. With the exception of some possible Valanginian (138 Ma) ice-rafted debris in South Australia there are no reported glacial deposits, even at high latitudes as far back as Late Permian (258 Ma). The Late Devonian to Middle Permian Ice Age, well known especially from the high-latitude southern supercontinent of

Gondwana is at a time of low atmospheric CO₂, judging from stomatal index (Figure 3). From then back to another ice age of the Late Ordovician, there is again little evidence of glacial facies (Hambrey and Harland, 1981), and indications from paleosols of high CO₂ (Mora *et al.*, 1996). The fossil record of ice-disrupted soils, or Gelisols, and associated tundra and taiga ecosystems, also supports evidence from glacial facies for a reduced cryosphere at times of global warming (Retallack, 2001).

Biotic Consequences of Past Global Warming

The various environmental effects of global warming outlined above are closely interrelated with a variety of biotic changes recorded in the fossil record. As with environmental consequences, many biotic consequences are interrelated.

Reduced Plant Transpiration

Times of high CO₂ are not only times of low stomatal index (Figures 1f, and 2a), but also times of reduced stomatal aperture and of increased cuticle thickness of leaves (Retallack, 2002). These effects appear to be direct plant responses to high CO₂ levels, and lessened demand for air intake at the stomate. The effect of all these changes is to reduce transpiration of water by vegetation, which in turn lowers atmospheric moisture, raises soil water tables, and increases stream runoff (Beerling, 2005).

Increased Plant Sclerophylly

Times of high CO₂ are marked by an abundance of photosynthetic shoots rather than leaves, of needle-leaves rather than broadleaves, and of densely veined leaves rather than loosely veined leaves (Beerling, 2005; Retallack, 2005c). These various indications of increased sclerophylly may be a response to declining soil nutrient status with soil acidification or to increased plant consumption by animals and pathogens.

Increased Leaf Herbivory

Large collections of fossil leaves commonly contain examples of a variety of insect and fungal damage, but the proportion of damaged leaves is greater at times of high CO₂ (Wilf *et al.*, 2001). Increased abundance of fungi at times of high CO₂ is also indicated by sclerotinite in coals and spores and hyphae in palynofloras (Retallack and Krull, 2006). This may be a secondary effect of the greater primary and secondary productivity ecosystems under warmer and wetter conditions, or perhaps also a consequence of the spread to higher latitudes of animals and pathogens formerly limited by seasonal freezing.

Tropical Plant Geographic Expansion

The spread into polar regions of tropical plants such as palms with large frost-insensitive terminal meristems at times of high CO₂ is probably a consequence of global warming. Such geographic expansion of tropical plants has been especially

important for North American broadleaf vegetation, which contains many Asiatic and European taxa which migrated via Beringian and North Atlantic land bridges and islands (Wing, 1998).

Tropical Animal Geographic Expansion

Times of high CO₂ and mild polar climates also enabled migration to high latitudes of tropical animals such as primates and crocodiles (Markwick, 1994). As for plants, such migrations also allowed transcontinental biotic interchange via high-latitude land bridges such as Beringia (Clyde and Gingerich, 1998).

Helical Animal Burrows

Helical animal burrows are rare in the fossil record, presumably requiring more effort than straight ramps. Helical burrows are common at times of high CO₂ and global warming, perhaps because helicoidal airflow is self-ventilating (Meyer, 1999).

Wetland Eutrophication

Wetland paleosols at times of high CO₂ include minerals such as siderite and berthierine indicating unusually anoxic conditions in close association with root traces and burrows (Sheldon and Retallack, 2002). Atmospheric hypoxia may explain these differences, but so could increased microbial productivity under warmer and wetter conditions, because microbial respiration depletes oxygen from stagnant groundwater.

Oceanic Eutrophication

Times of high CO₂ are also times of black, pyritic shales with paper clams and other fossils tolerant of hypoxia (Knoll *et al.*, 1996), reduced area and extinction of tropical coral reefs (Wiedlich *et al.*, 2003), and blooms of microfossil dinoflagellates and diatoms (Siesser, 1995). These geological observations could be consequences of oceanic eutrophication with nutrient cations from increased terrestrial weathering, but also plausible is direct chemical reduction from an hypoxic atmosphere (Retallack and Krull, 2006), coral death by bleaching as zooxanthellae were expelled in warming water (Wiedlich *et al.*, 2003), and phytoplankton blooms tracking increased climatic seasonality (Siesser, 1995).

Conclusions

Anthropogenic global warming due to atmospheric pollution by CO₂ and CH₄ is commonly regarded as unprecedented, but the rock and fossil record indicates many comparable past atmospheric redox crises. Commonalities among these past events allow a better understanding of global warming induced by greenhouse gases. Biodiversity generally declined during geologically rapid global warmings due to CO₂ and CH₄ emissions from volcanic eruption and intrusion, meteorite impacts, or outbursts from submarine and permafrost

methane clathrates. Extreme cases of greenhouse release to the atmosphere are the great mass extinctions of the fossil record, when many creatures died from the effects of hypoxia, hypercapnia, and pulmonary edema. At lower levels of greenhouse gases, such lethal effects were limited in area to high altitudes, stagnant wetlands, oligotrophic coral reefs, and deep ocean basins. Some consequences of global warming such as increased precipitation and warmth extending to high-latitude intercontinental land bridges had the effects of increasing biodiversity. Hardships such as soil acidification and increased seasonality of climate selected for sclerophyllous, thickly cutinized plants. Hardships such as hypoxia selected for greater respiratory scope in animals. Such adaptations added to biodiversity. The effects on biodiversity of global warming by greenhouse gases are complex, but a rich fossil and rock record of comparable events in the past promises new perspectives on future global warming.

Glossary

Acetylcholinesterase (AChE) The enzyme responsible for breaking down the neurotransmitter acetylcholine (ACh) at nerve synapses, thereby preventing hyperexcitation of cholinergic pathways in the nervous system. The target of organophosphate and carbamate insecticides.

Bioassay (biological assay) A laboratory test for evaluating the response of organisms to a toxin and for diagnosing the presence or absence of resistance.

Cross-resistance The ability of a single gene or mechanism to confer resistance to more than one toxin.

Cytochrome P-450 monooxygenases A ubiquitous group of enzymes involved in the NADPH-mediated oxidation and metabolism of a broad range of endogenous and exogenous substrates.

GABA receptor Part of the inhibitory ion channel complex gated by GABA (γ -aminobutyric acid) in

postsynaptic nerve membranes. The target site of organochlorine insecticides and some other chemical groups.

Glutathione S-transferases (GSTs) Enzymes that catalyze the metabolism of a range of substrates following their conjugation with the endogenous tripeptide glutathione.

Multiple resistance The occurrence of more than one resistance mechanism in the same individual or pest population.

Sodium channel A large transmembrane protein that regulates the flow of sodium ions across axonal membranes and mediates the rising phase of action potentials. The target site of pyrethroid insecticides.

Synergist A chemical used at sublethal concentrations to inhibit particular groups of detoxifying enzymes and therefore to implicate these enzymes in resistance.

Introduction

The diversity of organisms and their genetic variation have been forged by evolution. In evolution, undirected mutations generate unstructured diversity, which is then structured by selection. The time scales over which selection and adaptation occur in eukaryotes are usually too large to observe *in situ* (except in a few cases, such as industrial melanism in some moths and ladybirds), but there is one microevolutionary process for which many of the factors driving selection and adaptation are well understood, a process that is being increasingly studied and manipulated by a large number of biologists. This is the phenomenon of pest resistance to insecticides, and its study can reveal much about how biodiversity originates, at the intraspecific level at least. Similar processes underpin the evolution of herbicide resistance by weeds, fungicide resistance by plant pathogens, and drug resistance by disease-causing microbes.

Extent of Resistance

Although a relatively recent phenomenon (resistance to the first synthetic insecticide, dichlorodiphenyltrichloroethane or DDT, was initially reported in the 1940s), insecticide resistance is now very widespread. Available statistics (Figure 1) show that reports of resistant arthropod species increased almost exponentially between 1950 and 1980, following the successive introduction of different classes of synthetic insecticides. By 1990, more than 500 species were reported to resist chemicals of at least one insecticide class, and many of these resisted several classes simultaneously. Of the resistant

species reported in 1990, 88% were insects (class Insecta) and 12% were mites and ticks (class Arachnida, order Acarina). Four insect orders – Coleoptera (beetles), Diptera (true flies), Hemiptera (aphids, bugs, hoppers, and whiteflies), and Lepidoptera (moths) – accounted for 92% of the resistant insect species; the remainder mostly comprised of cockroaches, thrips, lice, and fleas. Additional resistant species have been reported since 1990, but a change in survey methods makes it difficult to extend the temporal trend evident in Figure 1.

Although almost all insecticide classes are now affected by resistance, its extent varies greatly between species. In some insects, resistance only extends to a few closely related compounds in a single class; it may be very weak or restricted to a small part of their geographical range. At the other extreme,

Figure 1 Increase in the number of arthropod species reported to resist insecticides over time, in total, and in response to the four most widely used classes of insecticide (courtesy GP Georgioui).

Figure 2 Examples of arthropod pests that have developed resistance to insecticides, (a) The bollworm, *Helicoverpa armigera*, a major pest of cotton and vegetables in the Old World; (b) the tobacco or cotton whitefly, *Bemisia tabaci*, which threatens a wide range of crops through direct-feeding damage and the transmission of virus disease; (c) the peach-potato aphid, *Myzus persicae*, a major pest of vegetable and ornamental crops in temperate countries; and (d) the two-spotted spider mite, *Tetranychus urticae*, a cosmopolitan pest of fruit, vegetable, and ornamental crops.

some widespread pests such as the cotton bollworm (*Helicoverpa armigera*; **Figure 2(a)**), the tobacco whitefly (*Bemisia tabaci*; **Figure 2(b)**), the peach-potato aphid (*Myzus persicae*; **Figure 2(c)**), and the two-spotted spider mite (*Tetranychus urticae*; **Figure 2(d)**) can resist most or all of the insecticides available for their control. The most extensively used insecticide classes – organochlorines, organophosphates, carbamates, and pyrethroids – have generally been the most seriously compromised by resistance, and many principles relating to the origin and evolution of resistance can be demonstrated solely by reference to these fast-acting neurotoxins. In recent years, however, there has also been a worrying increase in resistance to more novel insecticides, including ones attacking the nervous system (e.g., neonicotinoids), developmental pathways (e.g., benzoylphenylureas), respiratory processes (e.g., mitochondrial electron-transport inhibiting

(METI) acaricides), and digestive systems (e.g., *Bacillus thuringiensis* (Bt) endotoxins).

Origins of Resistance

As insecticides are not normally considered mutagenic at field application rates, it is assumed that resistance mutations occur independently of insecticide exposure, and are as likely to occur before an insecticide is introduced as they are during its use in the field. Resistance is therefore a preadaptive phenomenon reflecting the selection of individuals possessing heritable genetic traits that promote their survival or reproduction in environments treated with insecticides. Estimates of mutation rates are as imprecise as they are for other adaptive traits, but will depend on the mutational event involved

(see Mechanisms of Resistance). The role of enzyme induction in resistance has not been demonstrated satisfactorily but is likely to be only of secondary importance. Increased tolerance due to environmental or biological factors such as diet, age, or climate can sometimes be significant but is outside the scope of this article.

Mechanisms of Resistance

Some of the most significant recent progress in understanding resistance result from applying advances in molecular biology to resistance research. Depending on the mechanism involved, resistance can arise through structural alterations of genes encoding target-site proteins or detoxifying enzymes, or through processes affecting the expression of gene products (e.g., gene amplification or altered transcription rates). Other mechanisms that have been demonstrated or postulated include reduced penetration of insecticides through the insect cuticle, enhanced excretion of insecticides, and behavioral traits enabling pests to reduce or avoid exposure to a toxin. However, the latter are generally considered to be relatively minor in effect or to arise only under very specialized circumstances. **Figure 3** is a schematic representation of some of the resistance mechanisms discussed in the following two sections.

Increased Detoxification of Insecticides

The three major routes of detoxification implicated in resistance are as follows: Enhanced metabolism of insecticides by cytochrome P-450 monooxygenases can potentially confer resistance to most chemical classes. Previously, much of the evidence for this mechanism was indirect, based on the ability of compounds such as piperonyl butoxide, which are known inhibitors of monooxygenases, to reduce the magnitude of

resistance when used as synergists in bioassays. However, recent developments in insect genomics are enabling complex families of genes such as those encoding monooxygenases to be cloned and characterized and single enzymes to be implicated directly in resistance through crossing studies and experiments on insecticide metabolism and binding.

Enhanced activity of glutathione S-transferases (GSTs) is considered potentially important in resistance to some classes of insecticide, including organophosphates. However, information on the role of GSTs in resistance is still sketchy but these enzymes, like monooxygenases, exist in numerous molecular forms with distinct properties, and are proving amenable to molecular screening and characterization.

Enhanced hydrolysis or sequestration by esterases (e.g., carboxylesterases) capable of binding to and cleaving carbonyl ester and phosphotriester bonds undoubtedly plays a significant role in resistance to organophosphates and pyrethroids. Of the three main types of detoxification mechanisms, this has historically been the best characterized biochemically. Resistance due to increased esterase activity can arise through either a qualitative change in an enzyme, improving its hydrolytic capacity, or (as in mosquitoes and aphids) a quantitative change in the titer of a particular enzyme that already exists in susceptible insects.

Alterations to Insecticide Target Sites

Resolving target-site modifications that lead to resistance requires some knowledge of the mode of action of insecticides themselves. At present, this information is most advanced for insecticides binding to enzymes or receptors in the nervous system of arthropods. Three examples of target-site resistance are well understood:

Organophosphates and carbamates exert their toxicity by inhibiting the enzyme acetylcholinesterase (AChE), thereby

Figure 3 Schematic diagram of a nerve synapse showing examples of insecticide-resistance mechanisms. (a) Changes in the structure of the sodium channel confer knockdown resistance (kdr) to pyrethroids. (b) Modified acetylcholinesterase (AChE) is no longer bound by organophosphates and remains available to breakdown acetylcholine molecules after neurotransmission across the synapse. (c) Detoxifying enzymes degrade or sequester insecticides before they reach their targets in the nervous system.

impairing the transmission of nerve impulses across cholinergic synapses. Mutant forms of AChE showing reduced inhibition by these insecticides have been demonstrated in several insect and mite species. Biochemical and molecular analyses of insecticide-insensitive AChE have shown that pests may possess several different mutant forms of this enzyme with contrasting insensitivity profiles, thereby conferring distinct patterns of resistance to these two large insecticide classes.

Pyrethroids act primarily by binding to and blocking the voltage-gated sodium channel of nerve membranes. A resistance mechanism causing insensitivity of this target site was first identified in houseflies (*Musca domestica*) and termed knock-down resistance (kdr). Kdr is attributable to structural modifications of the sodium channel protein and the genetic mutations responsible have been identified. This mechanism has been found in many pest species. As with insensitive AChE, there can be different forms of kdr resistance (e.g., a more potent "super-kdr" form in which a second mutation potentiates the level of resistance conferred by the original one).

GABA receptors are targets for several insecticide classes, including cyclodienes (a subclass of the organochlorines), avermectins, and fipronils. The primary mechanism of resistance to cyclodienes and fipronils involves modification of a particular GABA receptor subunit, resulting in substantial target-site insensitivity to these insecticides.

Homology of Resistance Genes

Although there are several possible mechanisms, the options for resisting insecticides can also be very limited, especially for mechanisms based on decreased sensitivity of insecticide target sites. The target-site mechanism of cyclodiene resistance involves the same amino acid substitution (alanine-302 to serine) in GABA receptors of several species of diverse taxonomic origin, including beetles, mosquitoes, whiteflies, and aphids. Work on the two other principal target-site mechanisms – altered AChE and kdr – has proved more challenging due to the occurrence of multiple resistance alleles at the same loci. In the case of kdr, however, there is also evidence for the same amino acid substitution (leucine-1014 to phenyl-alanine) in the sodium channel protein conferring a "basal" kdr phenotype in a wide range of species. This phenotype can be enhanced (to "super-kdr" resistance) by further mutations that also recur between species. Despite the structural complexity of the receptors involved, these parallel mutations imply that the opportunities for insects to modify them to avoid or reduce binding of insecticides, while retaining normal functioning of the nervous system, are very limited indeed.

When susceptible individuals of the sheep blowfly (*Lucilia cuprina*) were exposed to the mutagen ethyl methanesulfonate (EMS) and their progeny screened for resistance to dieldrin (a cyclodiene), surviving insects not only exhibited a GABA receptor-based mechanism analogous to that found in nature but also exhibited an identical alanine to serine amino acid substitution in the receptor gene. Similarly, mutagenesis followed by screening with diazinon (an organophosphate) led to the recovery of a resistance mechanism showing identical toxicological, biochemical, genetic, and molecular properties to one that had previously evolved to diazinon under field

conditions. These findings reinforce the tight evolutionary constraints on the number of viable resistance mutations, even in the laboratory, where mutations conferring deleterious effects on overall fitness might be expected to survive better than in the open field. Interestingly, they also highlight the potential of using mutagenesis to predict likely resistance mechanisms to novel insecticides in advance of them being used commercially and to tailor resistance-management recommendations accordingly.

In other cases, different types of resistance to the same toxin exist and can account for differences in the toxicological and genetic basis of resistance between species or between different geographical populations of the same species. Insecticidal proteins from the soil bacterium Bt are becoming increasingly important in pest management, especially in relation to insect-tolerant transgenic crops (see The Special Case of Transgenic Plants). To date, the only species to have evolved Bt resistance on a large scale in the field is the diamondback moth, *Plutella xylostella*. The majority of Bt-resistant populations examined have exhibited very similar characteristics, including a very consistent pattern of cross-resistance to different Bt toxins and recessive inheritance. However, there are also strains of *P. xylostella* in which the breadth and inheritance of Bt resistance differ markedly from this "mode," implying the existence of distinct resistance genes and mechanisms.

How often do Resistance Genes Arise?

The recurrence of specific resistance mutations within and between taxa begs another question of fundamental significance to the origins of biodiversity: Have such mutations arisen repeatedly within the same species, or appeared on only a limited number of occasions and subsequently spread through migration or human agency? This question is amenable to investigation by sequencing not only the resistance genes themselves but also flanking regions and introns, which would be expected to vary between alleles that have arisen independently. In the mosquito, *Culex pipiens*, organophosphate resistance is primarily conferred by allozymes at two closely linked loci (esterases A and B) coding for insecticide-detoxifying carboxylesterases. Overproduced allozymes (resulting from amplification of A or B genes) tend to recur in geographically disjunct areas. This situation could be explained by recurrent mutation generating each amplification event *de novo* or by a nonrecurrent mutation that has subsequently spread between populations. Restriction mapping of DNA around the esterase genes points to the latter explanation, with large-scale gene flow (even between continents) most likely attributable to passive migration of mosquitoes on ships or airplanes. It is notable that the appearance of a new resistance allele in southern France originated in the vicinity of the international airport and seaport at Marseilles.

Organophosphate resistance in the aphid *M. persicae* is also attributable to the amplification of a gene encoding an insecticide-detoxifying carboxylesterase. Despite the often widespread dispersion of these amplified genes in the aphid genome, restriction analyses have indicated that all copies are in the same immediate genetic background. This suggests that

amplification occurred only once, with the amplified DNA subsequently being moved intact around the genome through chromosomal rearrangements, or perhaps mediated by transposable elements. Similarities in the position and structure of these genes in aphids of diverse geographic origin reinforce the likelihood of a single amplification event that has subsequently become widely dispersed around the world.

However, there is also molecular evidence for some resistance genes having several independent origins in the same species (e.g., for target-site resistance to cyclodienes in the red flour beetle, *Tribolium castaneum*). Results for mosquitoes and aphids, nonetheless, highlight the potential for large-scale inadvertent movement of resistant insects between countries or even continents. For crop pests, these risks are particularly acute due to the increasing international trade in edible and ornamental plants, many of which have been treated with insecticides at their point of origin. In such cases, growers at the receiving end of the trade network face a dual threat: (1) the establishment of new pest species or more aggressive biotypes of existing ones and (2) the possibility that such pests are already strongly resistant to compounds that might otherwise be used to suppress or eradicate them.

Cross-Resistance and Multiple Resistance

Arthropods seldom resist just one toxin. Most commonly, they exhibit differing levels of resistance to a range of related and unrelated insecticides. In its strictest sense, the term “cross-resistance” refers to the ability of a single mechanism to confer resistance to several insecticides simultaneously. A more complex situation is that of “multiple resistance,” reflecting the coexistence of two or more resistance mechanisms, each with their own specific cross-resistance characteristics. Distinguishing cross-resistance from multiple resistance is a challenging aspect of resistance research. However, knowledge of the mechanisms involved is often essential in order to develop resistance-management recommendations based, for example, on the alternation of insecticides to avoid continuous selection for the same resistance gene or mechanism.

Unfortunately, cross-resistance patterns are inherently difficult to predict in advance, because mechanisms based on both increased detoxification and altered target sites can differ substantially in their specificity. The most commonly encountered patterns of cross-resistance tend to be limited to compounds within the same chemical class (equivalent to the term “side resistance” as used by parasitologists). However, even these patterns can be very idiosyncratic. For example, organophosphate resistance based on increased detoxification or target-site alteration can be broad-ranging across this group or highly specific to a few chemicals with particular structural similarities. The breadth of target-site resistance to pyrethroids also depends on the resistance allele present. The most frequent mutation affects almost all compounds in this class to a similar extent (approximately 10-fold resistance), whereas resistance due to other mutations is highly dependent on the alcohol moiety of pyrethroid molecules, ranging from approximately 10-fold to virtual immunity. Cross-resistance between insecticide classes is even harder to anticipate, especially for broad-spectrum detoxification systems whose specificity

depends not only on insecticides having the same mode of action but also on the occurrence of common structural features that bind with detoxifying enzymes.

Empirical approaches for distinguishing between cross-resistance and multiple resistance include (1) repeated backcrossing of resistant populations to fully susceptible ones to establish whether resistance to one chemical cosegregates consistently with resistance to another and (2) reciprocal selection experiments whereby populations selected for resistance to one chemical are examined for a correlated change in response to another. If available, biochemical or molecular diagnostics for specific resistance genes can assist considerably with tracking the outcome of genetic crosses or with assigning cross-resistance patterns to particular mechanisms.

Diagnosis of Resistance

A large number of laboratory bioassay methods (e.g., **Figure 4(a)**) have been developed for detecting and characterizing resistance.

Figure 4 Examples of resistance diagnostics for the peach-potato aphid, *Myzus persicae*; (a) a bioassay in which insecticide droplets are applied topically to individual aphids; and (b) a biochemical immunoassay to determine levels of an insecticide-detoxifying esterase in individual aphids. The top row shows results for three insects from each of four resistance categories, with resistance increasing from left to right. The remaining insects were drawn randomly from a field sample.

Most of these are limited to defining phenotypes and provide little or no information on the underlying genes or mechanisms. Thus, although bioassays remain the mainstay of most large-scale resistance monitoring programs, much attention has been paid to develop more incisive techniques that not only offer greater precision and throughput but also diagnose the type of mechanism(s) present and, whenever possible, the genotypes of resistant insects. A variety of approaches are being adopted for this purpose, including electrophoretic or immunological detection of resistance-causing enzymes, kinetic and end-point assays for quantifying the activity of enzymes or their inhibition by insecticides, and DNA-based diagnostics for mutant resistance alleles. The sensitivity that these techniques can provide is exemplified well by work on the aphid *M. persicae*, which in northern Europe possesses at least three coexisting resistance mechanisms: (1) an overproduced carboxylesterase conferring resistance to organophosphates, (2) an altered AChE conferring resistance to certain carbamates, and (3) target-site (*kdr*) resistance to pyrethroids. These mechanisms collectively provide strong resistance to virtually all available aphicides. Fortunately, it is now possible to diagnose all three in individual aphids using an immunoassay for the overproduced esterase (**Figure 4(a)**), a kinetic microplate assay for the mutant AChE, and a DNA-based diagnostic for the *kdr* allele. The combined use of these techniques against field populations provides up-to-date information on the incidence of the mechanisms and is used to alert growers to potential control problems.

Selection of Resistance Genes

The rate at which resistance genes are selected reflects the combined influence of numerous biotic and abiotic factors. Resistance offers several advantages for research to resolve these factors and their interactions. First, the selecting agent (exposure to insecticides) is well understood; it can usually be carefully documented using treatment histories or manipulated to investigate its effect on selection rates. Second, the selective advantages conferred by resistance genes are often very large, leading to substantial changes in genetic composition over a measurable time frame. Third, most of the major mechanisms of insecticide resistance, unlike those for many stress-related adaptations, are controlled by single genes of major effect (monogenic) rather than many genes, each of small effect (polygenic). This renders resistance more readily amenable to analysis within the theoretical framework of ecological genetics. Finally, the frequent availability of bioassays for quantifying the frequency of resistance phenotypes, or even *in vitro* assays for specific genotypes, enables accurate documentation of responses to selection applied in population cages in the laboratory or under open field conditions.

Factors determining the selection (and hence risk) of resistance to insecticides can, for convenience, be classified into genetic or ecological ones relating to the intrinsic properties of pests and resistance mechanisms and operational ones relating to the chemical itself and how it is applied. Some of the most important factors apparent from the large body of experimental and theoretical research on resistance selection are summarized in the following three sections.

Genetic Influences

For resistance to evolve, resistance genes must confer a selective advantage over their susceptible counterparts. One of the primary challenges for describing resistance is therefore to estimate the relative fitness of different genotypes under exposure to insecticides. There are different ways of achieving this, the most direct being to release individuals of known susceptible and resistance genotypes into insecticide-treated environments and to monitor their survival. This has been done for a variety of pest species and has identified many, often subtle, influences on how resistance genes are expressed in the field. The dominance of resistance genes, which exerts a major influence on selection rates, is a case in point. In laboratory bioassays evaluating the relative survival of susceptible homozygotes (SS), heterozygotes (RS), and resistance homozygotes (RR) over several insecticide concentrations, dominance can be measured precisely, with RS individuals usually responding in an intermediate manner. In the field, dominance is a changeable phenomenon, depending on the concentration of insecticide applied and its uniformity over space and time. Even when the initial concentration is sufficient to kill RS individuals (rendering resistance effectively recessive), the weathering or decay of residues may result in this genotype showing increased survival and resistance becoming functionally dominant in expression. When resistance genes are still rare, and hence mainly present in heterozygous condition, this can have a profound effect in accelerating the selection of resistance genes to economically damaging frequencies.

The diverse mating systems of insects also influence the rate at which resistance evolves. Although most research has focused on outcrossing diploid species (typified by members of the Lepidoptera, Coleoptera, and Diptera), systems based on haplodiploidy and parthenogenesis also occur among key agricultural pests. In haplodiploid systems, males are produced uniparentally from unfertilized, haploid eggs, and females are produced biparentally from fertilized, diploid eggs. The primary consequence of this, exemplified by whiteflies (**Figure 3(b)**), spider mites (**Figure 3(c)**), and phytophagous thrips, is that resistance genes are exposed to selection from the outset in haploid, hemizygous males, irrespective of intrinsic dominance or recessiveness. Whether a resistance gene is dominant, semidominant, or recessive, resistance can develop at a similar rate under haplodiploidy, whereas recessiveness can cause significant delays (initially at least) in diploid populations.

Most species of aphid undergo periods of parthenogenesis, promoting the selection of clones with the highest levels of resistance or the most damaging combination of resistance mechanisms. However, in holocyclic populations (ones that alternate between sexual and asexual reproduction), this effect is at least partially countered by genetic recombination and the subsequent reassortment of mechanisms during sexual reproduction. In fully anholocyclic (asexual) populations, such as those of *M. persicae* in northern Europe, the influence of parthenogenesis is much more severe and has led to strong and persistent associations between resistance mechanisms within clonal lineages exposed to a succession of different selecting agents.

Ecological Influences

Several aspects of pest ecology, including the dynamics, phenology, and dispersal capabilities of pest organisms, act as primary determinants of resistance development. However, their influence on selection rates can be unpredictable without a sound knowledge of how they interact with patterns of insecticide use. As an example, movement of pests between untreated and treated parts of their range may delay the evolution of resistance, due to the diluting effect of susceptible immigrants. Conversely, large-scale movement can also accelerate the spread of resistance by transferring resistance alleles between localities.

For highly polyphagous crop pests, interactions between pest ecology and insecticide treatments play a particularly critical role in determining selection pressures. Key factors to be considered are the seasonality and relative abundance of treated and untreated plant hosts and patterns of migration between hosts at different times of the year. A good example relates to the two major bollworm species (Lepidoptera: Noctuidae) attacking cotton in Australia. Only *H. armigera* (Figure 3(a)) has developed a strong resistance; *H. punctigera*, despite being an equally important cotton pest, has remained susceptible to all insecticide classes. The most likely explanation is that *H. punctigera* occurs in greater abundance on a larger range of unsprayed hosts than *H. armigera*, thereby precluding a significant increase in resistance on treated crops.

However, polyphagy can sometimes be deceptive. In the cotton/vegetable/melon production systems of the southwestern USA, the highly polyphagous whitefly *B. tabaci* has become a devastating pest and a primary target of insecticide sprays. The consequences for resistance have varied substantially on a regional basis. Resistance problems have proved much more severe and persistent on cotton in south-central Arizona than in the extreme southwest of the state and the adjacent Imperial Valley of California. This appears attributable to the higher proportion of unsprayed hosts, especially alfalfa, acting as a buffer to resistance in the latter areas and preventing any directional increase in the severity of resistance over successive seasons. In south-central Arizona, these untreated refuges are much less abundant during the time that cotton is treated with insecticides. Thus, a large proportion of the local whitefly population is forced through a selection "bottleneck" on cotton and exposed to intense selection for resistance, despite an abundance of alternative hosts at other times of the year.

Enclosed environments, such as greenhouses and glass-houses, which restrict migration and escape from insecticide exposure under climatic regimes favoring rapid and continuous population growth, provide ideal ecological conditions for selecting resistance genes. Very low or zero damage tolerance thresholds for high-value ornamental or vegetable produce accentuate the problem by promoting overfrequent spraying and hence intensify selection for resistance. Over the years, these environments have proved potent sources of novel resistance mechanisms for a diverse range of control agents and have presented a particular challenge to attempts at resistance management.

Operational Influences

Although closely linked to the aspects of pest genetics and ecology, operational factors are best distinguished as ones which, in principle at least, are at human's discretion and can be manipulated to influence selection rates. Factors exerting a major influence in this respect include the rate, method, and frequency of applications, their biological persistence, and whether insecticides are used singly or as mixtures of active ingredients.

Equating operational factors with selection is often difficult, because without a detailed knowledge of the resistance mechanisms present it is impossible to test many of the assumptions on which genetic models of resistance are based. Anticipating the selection pressure imposed by a particular application dose of insecticide is a case in point. If resistance alleles are present, the only entirely nonselecting doses will be ones sufficiently high to overpower all individuals, regardless of their genetic composition, or ones sufficiently low to kill no insects at all. The latter is obviously a trivial option. Prospects of achieving the former depend critically on the potency and dominance of resistance genes present. A pragmatic solution to this dilemma is to set application doses as far above the tolerance range of SS individuals as economic and environmental constraints permit, in the hope that at least RS genotypes will be effectively controlled. Even this approach can backfire badly if resistance turns out to be more common than suspected (resulting in the presence of RR homozygotes) or resistance alleles exhibit an unexpectedly high degree of dominance. Unless a high proportion of insects escape exposure altogether, the consequence could then be to select very rapidly and effectively for homozygous resistant populations.

In practice, concerns over optimizing dose rates to avoid resistance are secondary to ones regarding the application process itself. Delivery systems or habitats promoting uneven or inadequate coverage will generally be more prone to selection for resistance, because pests are more likely to encounter exposure conditions under which selection is most intense. This was elegantly demonstrated through experiments assessing the relative survival of endosulfan-susceptible and -resistant phenotypes of the coffee berry borer (*Hypothenemus hampei*) in coffee plantations treated with this chemical in New Caledonia. The practice of spraying plantations from roadsides with vehicle-mounted mistblowers generated gradients in the concentration of endosulfan that resulted in different selection pressures in different parts of each field. Similarly, underdosing with the fumigant phosphine in inadequately sealed grainstores has been implicated as a primary cause of resistance to this chemical in a range of stored product pests.

The timing of insecticide applications relative to the life cycle of a pest can also be an important determinant of resistance. A good example relates to the selection of pyrethroid resistance in the cotton bollworm, *H. armigera*, in Australia. On cotton foliage freshly treated with the recommended field dose, pyrethroids killed larvae up to 3–4 days old irrespective of whether they were resistant or not by laboratory criteria. As the sensitivity of larvae of all genotypes to pyrethroids was found to decline with increasing larval size, the greatest

discrimination between susceptible and resistant phenotypes occurred only when larvae achieved a threshold age. Targeting of insecticides against newly hatched larvae, as is generally advocated for bollworm control, not only increases the likelihood of contacting larvae at the most exposed stage in their development but also offers the greatest prospect of retarding resistance by overpowering its expression.

In practice, persistent insecticides are often essential to ensure an acceptable period of control, especially when contending with disease vectors or continued invasion of crop pests from alternative host plants. However, persistent applications can accentuate resistance development by exposing a larger number of individuals to the selecting agent. Another problem is that residues of persistent insecticides decay or become diluted through plant growth, so that resistant insects may survive more effectively than they did at the time of application. Empirical studies with a range of pests including mosquitoes, bollworms, and blowflies have demonstrated that aged deposits discriminate more readily between genotypes or phenotypes than ones freshly applied.

In theory, the coapplication of two or more unrelated chemicals as insecticide mixtures offers substantial benefits for delaying the selection of resistance. The underlying principle is one of "redundant killing," whereby any individual already resistant to one insecticide is killed by simultaneous exposure to another, and vice versa. However, achieving this objective requires not only that each type of resistance is still rare but also that the ingredients confer mutual protection throughout the effective life of an application. Failure to ensure that they exhibit similar biological persistence may lead to one compound exerting greater selection pressure than the other, thereby accelerating the selection of doubly resistant phenotypes. Two potentially conflicting challenges of choosing ideal mixture partners are therefore (1) to ensure maximum similarity in efficacy and persistence against the target pest(s) and (2) to ensure maximum dissimilarity in chemical structure and mode of action to minimize the likelihood of cross-resistance. Difficulties with identifying candidate molecules that meet all these criteria have greatly limited the use of mixtures for combating resistance to conventional insecticides, although they have considerable appeal for sustaining the effectiveness of insect-tolerant transgenic crops (*see* The Special Case of Transgenic Plants).

Fitness Costs Associated with Resistance

Despite the advantages they confer under exposure to insecticides, it is often assumed that resistance genes also confer physiological costs that could lead to counterselection when insecticides are not applied. Some of the best examples of such fitness costs come from studies conducted under harsh or stressful environmental conditions, when even slight differences in relative fitness are likely to have major consequences for the survival of genotypes. For example, resistant strains of bollworms, blowflies, and aphids have all been demonstrated to overwinter less successfully than their susceptible counterparts. Possible explanations for these fitness differentials include the reduced viability of certain life stages, a slower reproductive rate rendering resistant insects more vulnerable to adverse climatic conditions or to predation, or a reduced

ability to respond to environmental cues promoting survival. In the aphid *M. persicae*, resistant individuals are less inclined to move from senescing to younger leaves and are therefore more vulnerable to isolation and starvation after leaf abscission. Many resistant aphids also appear less able to avoid attack by parasitoids and predators – a more subtle side-effect with interesting implications for combining chemical and biological control strategies.

Fitness costs associated with resistance can be difficult to demonstrate experimentally, since deleterious effects may only be expressed under particular environmental conditions or be conferred by other genes closely linked to the resistance locus. The most convincing examples are ones in which costs have been found consistently in resistant populations of diverse geographic origin or have persisted after several generations of back-crossing to susceptible insects in order to exclude linkage effects. The potential for fitness drawbacks to be overcome by a process of coadaptation, i.e., the integration of resistance genes with other "modifier" loci that ameliorate fitness costs, has also proved challenging to demonstrate. In a few cases, however, repeated back-crossing of resistant insects to susceptible ones has led to seemingly fit resistance phenotypes acquiring a fitness penalty, apparently due to the uncoupling of resistance genes from modifier loci.

Combating Insecticide Resistance

In most studies of evolution, the primary challenge is to identify selective forces and to interpret their effects on the genetic composition of individuals and populations. With insecticide resistance, it is also necessary to intervene in the evolutionary process and find ways of reducing its deleterious impact on pest management. Failure to do so in the past has had many severe consequences, including the economic failure of cropping systems, the resurgence of insect-transmitted pathogens, and damage to the environment by way of increased insecticide applications.

The concept of insecticide-resistance management (IRM) aims to address these concerns through the development of control strategies for overcoming resistance to currently used compounds, or preventing its appearance in the first place. Although drawing extensively on the theoretical and empirical framework that evolutionary biology provides, IRM strategies must also contend with several practical, economic, and political constraints on the choice of possible management tactics and the precision with which they can be applied. The most important of these are as follows:

1. The properties of any resistance genes present will often be unknown, and knowledge of pest ecology may still be rudimentary.
2. It is often necessary to contend with a whole pest complex rather than just a single pest species.
3. There will often be a very limited number of insecticides available for use in management strategies.
4. For highly mobile pests at least, countermeasures may need to be standardized and synchronized over large areas, sometimes whole countries.
5. Resistance is a dynamic phenomenon; i.e., any mechanisms already known to exist may change over time.

Continued monitoring is vital to determine whether management recommendations remain valid or need to be revised in light of changing circumstances or new knowledge gained.

6. To promote compliance with management strategies, the countermeasure adopted should be as unambiguous, rational, and simple as possible.

A strategy first implemented on Australian cotton in 1983 to contend with the bollworm, *H. armigera*, illustrates many features of large-scale attempts at resistance management. It was introduced in response to unexpected, but still localized, outbreaks of pyrethroid resistance in *H. armigera* and was based primarily on the concept of insecticide rotation. The threat of pyrethroid resistance was countered by restricting these chemicals to a maximum of three sprays within a prescribed time period coincident with peak bollworm damage. Farmers were required to use alternative insecticide classes at other stages of the cropping season, in order to diversify the selection pressures being applied.

Compliance with this strategy was excellent, and initially it had the desired effect of preventing a systematic increase in the frequency of pyrethroid-resistant phenotypes. Additional recommendations resulting from work on the ecological genetics of pyrethroid resistance, including the targeting of insecticides against newly hatched larvae (when even resistant insects can be killed) and the plowing-in of cotton stubble to destroy resistant pupae overwintering in the soil, undoubtedly contributed to this success. Unfortunately, the restrictions placed on pyrethroid use were inadequate to prevent a gradual, long-term buildup of pyrethroid resistance. As a result, pyrethroids are no longer considered reliable control agents for *H. armigera*, although they remain highly effective against a coexisting species, *H. punctigera*. The strategy has therefore been revised extensively to place greater emphasis on distinguishing between the two *Helicoverpa* species and on the strategic use of nonpyrethroids against *H. armigera*. Transgenic cotton plants expressing Bt toxins have since become the mainstay for controlling *H. armigera* in Australia, and tactics for deploying these without selecting rapidly for Bt resistance were implemented at the outset.

Another strategy incorporating a wide range of chemical and nonchemical countermeasures was introduced on Israeli cotton in 1987. This had the primary objective of conserving the effectiveness of insecticides against the whitefly, *B. tabaci*. Under recommendations coordinated by the Israeli Cotton Board, important new whitefly insecticides were restricted to a single application per season within an alternation strategy optimized to contend with the entire cotton pest complex and to exploit biological control agents to the greatest extent possible. One major achievement of this strategy has been a dramatic reduction in the number of insecticide applications against the whole range of cotton pests, but especially against *B. tabaci*. Sprays against whiteflies now average less than two per growing season compared with more than 14 per season in 1986. Most importantly of all, the strategy has generated an ideal environment for releasing additional new insecticides onto cotton and for managing them effectively from the outset.

Given the threats posed by resistance to pest control, resistance management has become an increasing preoccupation among crop-protection scientists, and also

pesticide manufacturers and bodies that regulate the release and use of insecticides. Major agrochemical companies work jointly to publicize resistance through the global Insecticide Resistance Action Committee (IRAC). In the European Union, resistance risk assessment is an integral part of approving new products and maximizing their effective lifespan.

Resistance in Nonpest Species

Compared with its prevalence in arthropod pests, insecticide resistance is still relatively rare among nonpest species including beneficial organisms. However, it has been well documented in a few species of hymenopteran parasitoids and predatory mites, some of which are being exploited in integrated pest management (IPM) systems. Its rarity among beneficial organisms is probably due in part to difficulties in locating hosts and prey (and hence surviving) under exposure to insecticides. The likelihood of resistance developing in beneficial arthropods may be increased if the insects they depend on as prey are already resistant, although this requires further research. It is also likely that, in comparison with herbivorous species, the enzyme systems of predators and parasites are less well adapted to detoxify xenobiotics.

The propensity for beneficial insects to evolve resistance obviously depends on the degree of selectable variation within their populations. Although laboratory selection has been used to enhance low levels of pesticide tolerance found in field populations, there is a concern that such selection applied at artificially low doses will promote polygenic traits that could fragment and dissipate if released into natural populations. However, when substantial resistance has evolved naturally in the field, its mechanisms have tended to be similar to ones found in pest species. Organophosphate-resistant strains of the green lacewing, *Chrysopa scelestes*, have been shown to exhibit increased activity of acetylcholinesterase (AChE) compared with susceptible insects. A carboxylesterase enzyme, very similar in amino acid sequence to that conferring organophosphate resistance in the aphid, *M. persicae*, has been cloned and sequenced from a malathion-resistant strain of the parasitic wasp *Anisopteromalus calandrae*.

As the development of resistance is dependent on the ecology of systems in which it appears, interactions between beneficial and pest species will greatly affect the epidemiology and dynamics of resistance in both. For example, some parasitoids of stored-grain beetles are resistant to insecticides, and it is thought that this adaptation has been encouraged by the fact that their parasitic larvae are sheltered from insecticides by the grain kernels inhabited by their hosts. This is thought to protect a substantial part of the insect life cycle from insecticide selection and ensures that relatively small shifts in insecticide tolerance by the parasitoid afford significant protection against the decreased insecticide doses that do penetrate their defenses.

Natural enemies may contribute to retarding resistance in pest species by exerting sufficient control to decrease the number of insecticide treatments required. Conversely, there are ways in which natural enemies could promote the adaptation of pests to insecticides. For example, the selection pressure for resistance would be increased if weaker,

sublethally affected individuals were more easily preyed upon or parasitized than their fully resistant and therefore unaffected counterparts.

The Special Case of Transgenic Plants

A major development in crop protection with an important bearing on resistance is the release of crop plants genetically engineered to express genes for insecticidal toxins derived from the microbe *Bacillus thuringiensis* (Bt). Bt cotton and corn is already being grown commercially on a large scale in the USA, Canada, Australia, Mexico, South America, China, India, and South Africa. In 2006, the total area worldwide planted with Bt crops was estimated to exceed 28 million ha. Existing toxin genes in Bt cotton and corn are active specifically against certain key lepidopteran pests (especially bollworms and corn borers); another engineered into potatoes provides protection against the Colorado beetle, *Leptinotarsa decemlineata*.

Aside from their commercial prospects, insect-tolerant transgenic crops offer numerous potential benefits to agriculture. The incorporation of Bt genes into crops offers constitutive expression of toxins in plant tissues throughout a growing season. This could reduce dramatically the use of conventional broad-spectrum insecticides against insect pests as well as remove the dependence of pest control on extrinsic factors, including climate and the efficiency of traditional application methods. Estimates differ, but one study concluded that conventional insecticide use between 1996 and 2005 fell by more than 35 million kilograms of active ingredient, roughly equivalent to the amount applied per year to arable crops in the European Union. However, the high and persistent level of expression also introduces a considerable risk of pests adapting rapidly to resist genetically engineered toxins. To date, there have been no examples of large-scale control failures due to resistance selected directly by commercial transgenic crops, but resistance to conventional Bt sprays (selected in either the laboratory or the field) has been reported in more than a dozen species of insect. Research on the causes and inheritance of such resistance is providing valuable insights into the threats facing Bt plants and the efficacy of possible countermeasures.

Tactics proposed for sustaining the effectiveness of Bt plants have many parallels with ones considered for managing resistance to conventional insecticides. However, they are more limited in scope due to the long persistence and constitutive expression of engineered toxins and the limited diversity of transgenes currently available. Indeed, for existing "single-gene" plants, the only prudent and readily implementable tactic is to ensure that substantial numbers of pests survive in non-transgenic "refuges," composed either of the crop itself or of alternative host plants. The stacking (pyramiding) of two or more genes in the same cultivar, or possibly mixtures of cultivars expressing different single toxins, are potentially more durable options for resistance management. Whatever measures are adopted, it is essential that Bt plants (and their successors expressing other transgenes) are exploited as components of multitactic strategies rather than as a panacea for existing pest-management problems, including those arising from the development of resistance to conventional insecticides.

Concluding Remarks

Over the past 25 years, few areas of entomology have advanced as rapidly or received such widespread attention as that of insecticide resistance. Research on this topic has provided invaluable insights into the origin and nature of adaptations, and these are in turn proving of much broader significance for understanding genetic responses to manmade change in the environment. In many respects the continuing battle against resistance is analogous to an evolutionary "arms race," in this case pitting human ingenuity in discovering new toxins against the adaptive capacity of pest species. Debates as to who will eventually win this race are of secondary importance to the realization that for many species the race is probably unnecessary. A wider adoption of resistance-management practices, especially through greater exploitation of nonchemical measures, would assist with reducing both the economic impact of resistance and any deleterious effects of pest management on biodiversity in general.

Glossary

Eutrophication Overenrichment of aquatic systems with nutrients, often leading to harmful algal blooms and subsurface oxygen depletion.

Harmful algal blooms Development of sufficient numbers of cells of algal species to cause “harmful” effect to ecosystem.

Microbial response Expected responses of microscopic algae to nutrient enrichment is excess production beyond what can be consumed by grazers and species shift to noxious species; this expected response is not necessarily what happens.

Nutrient enrichment Usually excess of nitrogen and phosphorus nutrients to aquatic systems.

Redfield ratio From large-area and time averaging, ratio of carbon, nitrogen, phosphorus, and oxygen for normal ocean plankton and deep-ocean nitrate and phosphate pools.

Subsurface oxygen depletion Due to isolation of waters below the surface, metabolic breakdown of organic matter from the surface waters can cause depletion of dissolved oxygen concentration, leading to very low oxygen (hypoxia) or no oxygen (anoxia).

Introduction

Perhaps the single anthropogenic stress on aquatic and marine environments that is considered to be most ubiquitous is described with the broad term eutrophication. Human activities have mobilized nitrogen and phosphorus through agriculture, urban and suburban sewage, and atmospheric emissions sufficiently to greatly increase fluxes to aquatic environments, especially to lakes, estuaries, and coastal ocean waters. The overly simplistic view of eutrophication is that loading of nitrogen and phosphorus causes increased production and biomass of planktonic algae, with decreased species diversity. Thus, nutrient loading creates a stress to the aquatic community causing adverse community impact. Characteristic symptoms of eutrophication are depletion of oxygen in subsurface waters from excess algal biomass and development of blooms of noxious algal species (Richardson, 1997). Limnological studies of eutrophication have given concepts and observations about the phenomenon which, when applied to estuarine and coastal waters, often lead to incorrect conclusions. Contrary to simple models, nutrient loading in nearshore marine waters often does not support the level of primary production and phytoplankton biomass that would otherwise be expected from the high nutrient concentrations. Depletion of oxygen in subsurface waters is probably more a function of the physics of the specific aquatic system and lack of grazer consumption than it is of nutrient-stimulated excess algal growth. A bloom of a noxious algal species is probably more a function of the response by the entire aquatic community to the overall chemical milieu than it is to nutrient-stimulated growth of the algal species.

This lack of a simple cause-and-effect response to nutrient loading is especially important to evaluate in light of two essentially opposite resource management actions. In nearshore waters, the traditional approach to eutrophication is removal of nutrient inputs to prevent algal production and growth.

This approach has been successful in some cases. However, its success may be overestimated and probably, nutrient removal will have little of the intended impact in many estuarine and coastal waters. The second and opposite action with nutrient enrichment comes from recent proposals for large-scale engineering projects to fertilize waters of the open ocean to increase primary production (Cullen and Chisholm, 1999). In the one case, there is the simple goal of decreasing algal production (which is considered bad) by reducing nutrient inputs and in the other case a goal of increasing algal production (which is considered good) by adding nutrients; it's not that simple. A principal reason that we often misinterpret marine eutrophication is that insufficient consideration is given to the hydrodynamic and biogeochemical complexity of the environment as well as the biodiversity of the microbial community (Paerl, 1998).

In discussing biological diversity, Norse (1993) considers hierarchical levels that range from genetic to species to ecosystem. Stress appears to decrease community diversity, often also decreasing the number of species within an individual function, such as primary production. It is critical to consider that increased diversity at one trophic level may decrease diversity at another. An interesting example comes from a recent examination of thermal stress on a planktonic community. Microcosms were studied with examination of several trophic levels (Petchey *et al.*, 1999). It was found that environmental warming caused losses of top predators and herbivores, with increasing dominance by autotrophs and bacterivores. The warming increased extinction of predators with little effect on primary producers and bacterivores. Primary producer and bacterivore biomass increased, bacterial biomass did not change, and there were idiosyncratic impacts on total biomass. Warming directly increased primary production through temperature-dependent physiology and indirectly through changes in trophic structure. Warming also increased decomposition, probably both through physiology and

indirectly through food web structure. The results of this quantitative study are consistent with the general descriptive view of eutrophication where primary production and bacterial decomposition appear to increase while much of the rest of the trophic structure decreases (Vollenweider *et al.*, 1992).

Many anthropogenic inputs to the aquatic environment that may be considered potential stressors have a dual impact, both stimulating growth at low concentrations and decreasing growth at higher concentrations. At a functional level, like primary producers, it is well known that temperature has a stimulating influence on individual species until a threshold is reached, above which it can inhibit. There has been considerable interest recently about the influence of trace metals on primary producers showing this dual stimulating-inhibiting influence (Bruland *et al.*, 1991). The impact of nutrients is clearly similar if one looks at the full ecosystem. Overcoming limiting levels increases primary production and can increase entire ecosystem production, but only to an extent. Then too much nutrient loading may become a negative stress on the ecosystem. It is necessary to discriminate whether the effect is from nutrients or other inputs.

In the next section, the extension to the marine environment of the limnological example of eutrophication is examined. Following that is a section examining relatively low growth in high-nutrient environments and a section on ecosystem stoichiometry. The last section addresses the need for more thorough understanding of multiple stressor effects on the entire community, including grazer and trophic transfer.

Extrapolating from Lakes to the Sea

Lake Eutrophication

The classic example of reducing input of one nutrient to ameliorate eutrophication can be seen with the relatively successful cleanup effort that has taken place with lakes (e.g., Edmondson, 1991). Vollenweider's models of the 1960s have led to the single-element, phosphorus, approach to lake eutrophication. These were successfully applied to the experimental lakes program, where focus on P proved successful (Schlinder, 1981). In these studies, if carbon or nitrogen were in shortage, it could be brought in from atmospheric or sedimentary sources. Schlinder also concluded that micronutrients were not important except in rare cases. The accepted overview for lakes is that phytoplankton production is controlled by annual P-loading and that P-loading is directly related to P concentration and P concentration and chlorophyll are well correlated. Generalizations of this nature may be more valid for lakes than for marine and estuarine waters due to more thorough experimental information and the hierarchical approach used to study lake eutrophication (Hecky and Kilham, 1988). In addition, physical properties in estuarine and marine waters may make these systems more complex. Indeed, Schlinder (1981) has stated, "The control of eutrophication in estuaries has appeared to be much more complex than it is in lakes."

Estuarine and coastal ocean waters have considerable transport circulation driven by both tidal energy and riverine

discharge and this circulation is variable on predictable and unpredictable periodicities. These environments also have complicating factors from variations in suspended sediments through specific input sites, circulatory resuspension of bottom sediments, and coagulation along estuarine salinity gradients. Additionally, the salinity gradients of estuaries cause significant physical stress such that populations of organisms will change and moreover the change in ionic strength will influence chemical speciation and solute-solvent interactions. The more complicated and varying physics gives rise to less predictability of populations on a seasonal basis. This pertains not only to primary producers but also to food web structure. There is a large literature on the subject of coastal ocean eutrophication, with recognition of difficulties in applying eutrophication concepts to estuarine and coastal waters, where physics and biogeochemistry complicate the picture (Vollenweider *et al.*, 1992).

Food Web Complexity

In addition to the complicated nature of coastal waters, it is well recognized that food web structure can bring significant variability to all aquatic ecosystems, lakes as well as coastal marine waters. Schlinder *et al.* (1997) demonstrated that the primary production enhancement from nutrient enrichment was less in a piscivore-dominated lake than in a planktivore-dominated lake. The reason for this difference was the suppression of phytoplankton by large zooplankton in the piscivore lake. The study focus included evaluation of draw-down of atmospheric CO₂ from nutrient-enhanced production and confirmed that changes in aquatic CO₂ fugacity could be successfully manipulated in lakes and open-ocean ecosystems.

The recognition of complexity in oceanic microbial ecosystems led to the concept of the "microbial loop," where organic matter from phytoplankton is rapidly consumed by bacteria, which are in turn consumed by protozoans that are consumed by small zooplankton that otherwise would be herbivores exclusively (Azam *et al.*, 1989). This shunt from the phytoplankton-herbivore direct trophic transfer means lower efficiency in the path to higher metazoans and led to debates of bacteria as "source or sink" in oceanic as well as estuarine environments (Sherr *et al.*, 1987). Subsequent work with the microbial loop has led to considering the combined phytoplankton and microbial heterotrophs (bacteria and protozoans) as the primary producer community supporting the metazoans (Sherr and Sherr, 1991). With the primary producer function from a multicompartment ecosystem, it is not surprising to find phytoplankton and heterotrophic bacteria being influenced by different stimuli. For example, Pace (1993) showed bacteria being controlled by phosphorus while phytoplankton were controlled by nitrogen and phosphorus in lake nutrient enrichment experiments. In most cases with any aquatic environment, nutrient addition will bring variable influences on phytoplankton and heterotrophic bacteria and may also influence heterotrophic protozoans and metazoan grazers.

It has been well recognized that phytoplankton production, or the entire primary producer community, is

influenced by removal (top-down control) as well as by resource limitation (bottom-up control). In a recent review of eutrophication in planktonic ecosystems, Glibert (1998) pointed out that grazing and nitrogen recycling are intricately connected in controlling planktonic nitrogen availability. Another important recognition is that top-down control has a major impact on export from the pelagic system (Wassman, 1998). Wassman warned that to view only bottom-up controls (nutrient influence) will not successfully guide biogeochemical studies of marine systems. Thus, it seems obvious that a nutrient influence on phytoplankton should not be considered in the absence of the rest of the beginnings of the ecosystem.

Response of Nearshore Waters to Nutrient Enrichment

The idea that a single nutrient controls primary production comes from classical ecological theory. With a single nutrient, a single phytoplankton species should have an advantage over others and dominate by outcompeting. The fact that multiple species can coexist within an apparent niche was considered a paradox (Hutchinson, 1961) and was the subject of a massive amount of excellent aquatic research. Recognizing the necessity to consider guilds rather than a single species makes understanding of primary production more complicated. Add to this the more recent recognition that multiple compartments of phytoplankton plus bacterial and protozoan heterotrophs may be considered as a primary producer community, and the need for whole-ecosystem experiments is obvious.

There is an oversimplified view that nutrient concentrations (or loading) above those of some "pristine" condition directly cause phytoplankton response, with negative impact in estuarine and coastal waters. The overall impression is that increased nutrients cause increased algal growth with the consequence of excess algal production causing oxygen depletion or the consequence of a bloom of noxious algae. Oxygen depletion from nutrient-enriched phytoplankton growth occurs in environments where summer stratification isolates bottom waters, for example, Chesapeake Bay and mid-Atlantic coastal waters. Oxygen depletion is often quite variable on an innerannual basis and moderated by meteorological forcing. Thus, the occurrence and extent of oxygen depletion are complicated and not simply predictable as a function of nutrient loading.

There is concern that unusual and noxious algal blooms are increasing globally in both geographic extent and intensity, although there is debate on the quantitative significance of such claims (Anderson, 1997). It is important to be careful in defining harmful algal blooms (HABs) as Smayda (1997) has indicated. In most cases, the sign of the "bloom" is the appearance of numbers of cells of a species of a harmful alga sufficient to have a negative environmental impact. Analysis of individual HABs shows that generally the HAB taxa have no unique ecophysiology, including higher affinity for nutrients, and often that the HAB taxa have growth rates lower than those of phytoplankton in general (Smayda, 1997). Many HAB taxa have allelochemically enhanced competition with other algal species and have

allelopathic defense against predators as well as against a broad group of other microbial taxa. It appears that noxious algae bloom from their ability to dominate rather than their ability to outcompete other species for nutrients or to grow fast. What actually stimulates these taxa to express their domination is an area in need of more research. Full-ecosystem studies are needed to better understand noxious algal proliferations.

The experimental lakes program mentioned above has provided great empirical evidence to combine with theory in limnology. It is more difficult to manipulate whole parts of estuaries and coastal oceans than it is to do so with small lakes. Controlled mesocosms are a good compromise. The Marine Ecosystems Research Laboratory (MERL) at the University of Rhode Island has been one of the largest and most successful versions of realistic estuarine ecosystems (Oviatt *et al.*, 1986). In these, sufficient volumes of water have been used to overcome many problems of confinement and attempts have been made to simulate estuarine physical and biogeochemical influences. Some excellent research has been done and much learned about the complexity of estuarine responses to nutrients and other stressors.

A much used picture that was developed with information from the MERL experiments and from comparison of phytoplankton biomass and production in various estuaries and coastal waters has been shown by Nixon. The picture indicates phytoplankton increasing proportionately with increasing nutrient concentrations or loading. Figure 1(a) shows a generic version of this with phytoplankton production versus nitrogen loading. Note that the nitrogen loading is portrayed on a logarithmic scale (as was done in Nixon and Pilson, 1983), giving the appearance of regularly increasing production as a function of increasing nitrogen over a broad range of nutrient loadings. With transformation to a linear axis for N-loading, it is obvious that production becomes asymptotic after an initial linear increase. There have been several articles in which this conceptual picture has been shown and expanded upon; most of them are extensive evaluations of data from many published works, with the authors indicating that the relationship is complex (e.g., Nixon *et al.*, 1986). As has been cautioned by Nixon and others using it, the relationship is intended to cover a large range of nutrient conditions and to compare a number of different environments. However, a simplistic extension has been made suggesting that there is a simple linear relationship between nutrient loading and adverse phytoplankton production.

The behavior shown in Figure 1(b) is probably more correct to indicate that phytoplankton response to increased nutrients is not linear along a very long loading or concentration scale. Relatively small increases in nutrient concentrations and loadings will cause a large increase in primary production, but continued increases do not. In fact, it is likely that with very high nutrient concentrations a decreased phytoplankton response will be encountered as is shown with the theoretical curve in Figure 1(c). Thus, it is not necessarily the case that nutrient enrichment leads to excess algal production. Perhaps, we should be addressing the question of why there is not greater phytoplankton production in estuarine and coastal waters from nutrient enrichment.

Figure 1 Theoretical relationship of dissolved inorganic nitrogen loading to primary production. Frame (a) shows the often-depicted version with N-loading on a logarithmic scale, while transformation to a linear scale for N-loading is shown in frame (b). Frame (c) shows inhibition at high N concentration (note concentration rather than loading).

Nearshore Ocean Nutrient Response

The Oceanic HNLC Concept

Although it is well known that enhancement of primary production is not simply and directly proportional to enrichment by a single nutrient, there is a tendency to oversimplify this relationship in both nearshore and oceanic waters. I would like to use the oceanic HNLC (high nutrient, low chlorophyll) concept to examine enrichment of nearshore waters. The HNLC concept came from interest in iron limitation in the ocean that has a history going back to at least the 1920s (Martin *et al.*, 1990) but is best recognized in relation to Martin's proposed Antarctic and equatorial Pacific experiments (Coale *et al.*, 1996). Underlying the HNLC is the observation that some areas of the open ocean have relatively high concentrations of nitrogen and phosphorus nutrients but do not support proportionately large phytoplankton biomass; see Table 1. In open-ocean experiments, iron as a trace element added to overcome limitation has been shown to increase phytoplankton production with concomitant drawdown of atmospheric CO₂ in both the equatorial Pacific

Table 1

Characteristics of oceanic HNLC (high nutrient, low chlorophyll) environments

1. Relatively high concentrations of macronutrients
2. Low standing stock of phytoplankton
3. Moderate phytoplankton growth rates

Characteristics of estuarine HNLC (high nutrient, low growth) environments

1. High concentrations and fluxes of macronutrients
2. Moderate to high phytoplankton standing stock
3. Comparatively low phytoplankton growth rates
4. Sometimes, domination of flora by "undesirable" species

and the Antarctic oceans. The very nature of considering a trace constituent as critical to oceanic production indicates that the ecosystem is more complex than a simple cause-and-effect relationship with a major nutrient. In addition, the details of responses and trophic complexities in these oceanic experiments need more study before simple conclusions should be reached. However, this does not stop engineering plans for commercial fertilization of the ocean that are based on very simple cause-and-effect relationships. The same oversimplification in nearshore waters leads to proposals to solve eutrophication based upon very simple cause-and-effect relationships, i.e., reducing input of a single major nutrient.

An explanation for the observed HNLC conditions is the simultaneous control by grazing and micronutrients, such as iron. Cullen *et al.* (1992) have demonstrated with modeling for the equatorial Pacific upwelling region that grazing is the main control of standing stock but that a trace nutrient (e.g., Fe) might ultimately regulate overall productivity by influencing species composition and food web structure. Frost and Franzen (1992), with a chemostat model using a multiple-step food chain, demonstrate that simultaneous grazing control and trace nutrient limitation (e.g., Fe) could account for the observed conditions. Armstrong (1994) has shown with his multiple-species model that it is possible for each phytoplankton size class to be controlled by herbivores, while at the same time micronutrient limitation (e.g., Fe) may limit the number of size classes that can exist in a community and thus the total phytoplankton biomass that can be supported. A model has been presented (Armstrong, 1999) that shows HNLC conditions controlled by a combination of iron limitation of algal growth rates, ammonium inhibition of nitrate uptake leading to reduced uptake, and dependence of both processes on cell size. This dependence on cell size affects phytoplankton community structure and community uptake of nitrate. Recognition of the combined effect of a bottom-up influence (Fe limitation) and top-down influence (grazer control) would suggest that primary production in any aquatic environment has complex multiple controls.

High Nutrients and Low Growth in Estuaries

I suggest that we use a concept called HNLC (high nutrient, low growth) in estuarine waters that is similar to the oceanic HNLC, but with a different twist; see Table 1. A characteristic of the estuarine phenomenon is that phytoplankton show a

comparatively low growth rate and relatively high biomass. Probably a number of factors, individually or in combination, lead to the HNLC phenomenon. Proportions of macronutrients are often inappropriate for sustained high growth and limitation by micronutrients is also likely. Partial light limitation from algal biomass and from nonbiological suspended sediments also is involved in limiting growth. In addition, there is probably a negative influence on phytoplankton by contaminants and also inhibition of grazers by contaminants.

While lakes are generally considered P-limited, the traditional view is that marine waters are N-limited (Ryther and Dunstan, 1971). More recent evaluations have suggested that estuarine waters have alternating controls by nitrogen, phosphorus, and light. It is important to consider that nutrient enrichment is not necessarily an extension of nutrient limitation and that nutrient enrichment will not necessarily cause a direct proportional increase in phytoplankton. In some cases, fairly direct increases can be shown such as the indication that chlorophyll levels in the Chesapeake Bay have increased appreciably, with a doubling in dissolved inorganic nitrogen (DIN) over several decades. In contrast to this are examples in estuaries that do not show predicted increases. For example, Balls *et al.* (1996) show no change in chlorophyll in the Ythan River estuary between 1960 and 1990 when there was a fourfold increase in DIN. Alpine and Cloern (1992) showed a decline in primary production with increasing nutrient enrichment over time in the San Francisco Bay estuary. Reviewing conditions in a number of shallow coastal environments, Cloern (1999) showed a non-linear response between N-loading and phytoplankton production and suggested that the simple eutrophication model in lakes does not have a current analog in coastal eutrophication.

Examining data on DIN concentration versus measured primary production for summer estuarine transects along the Delaware Estuary, we can show a negative relationship (Figure 2). While I will not suggest that the high nitrogen concentrations directly cause a decrease in phytoplankton production, it is clear that there is not a simple continual

Figure 2 Primary production (integrated areal values as millimoles of C/m²/day) versus total dissolved inorganic nitrogen (DIN) concentration for samples along the full gradient of the Delaware Estuary. Composite data from summer samplings over 3 years. Highest DIN concentrations are found in the urban freshwater region of the estuary, with slightly lower values immediately upstream in the tidal freshwater region and downstream going into the salinity gradient. Lowest DIN concentrations are found in the lower estuary near the mouth of the Delaware Bay.

increase in production proportional to high nitrogen content. Note the similarity of Figure 2 to the theoretical Figure 1(c), where a small increase in DIN causes a large increase in production at concentrations near limiting, reaching an asymptote followed by a decline at very high DIN concentrations. To normalize measured primary production, the ratio of productivity to chlorophyll biomass (P/B) is often used. With data for the 1980s and 1990s from the Delaware Estuary, average summer P/B from the high-nutrient upper estuary is 61 (grams of C fixed per gram of chlorophyll) contrasted to the lower estuary production maximum region P/B value of 225 (Sharp *et al.*, unpublished data).

In most estuaries, nutrient increases have not been uniform. Often increases in DIN are accompanied by smaller increases or decreases in dissolved inorganic phosphorus (PO₄) such that the N/P ratio has increased. For example, this is the case with the nitrogen increases in the Chesapeake Bay and the Delaware Estuary (Sharp, 1998).

Stoichiometry

Redfield Ratios

From extensive averages of planktonic CNP composition and deep-ocean NO₃ and PO₄ nutrient concentrations, it was noted that a regular and predictable N/P ratio was found (Redfield *et al.*, 1963). This Redfield ratio concept was extended to carbon and oxygen for ecosystem utilization of elements. The concept has been extensively applied to aquatic systems for over a half century and is a valuable guide in understanding biogeochemical fluxes. Analysis of particulate CNP in a number of fresh-water lakes indicates that a variety of conditions exist, ranging from N and P deficiency to sufficiency (Hecky *et al.*, 1993). They concluded that ocean plankton is not as N and P deficient as is lake plankton. From a different viewpoint, Flynn (1990) concluded that only in the presence of excess NH₄ is the cellular response to N-stress fully suppressed. Thus, plankton throughout the ocean show some symptoms of N-stress. He suggested that there are three forms of N status: N-replete (no stress), N-sufficiency (enough stress to depress NO₃ transport and assimilation), and N-deplete (maximum stress, no growth). With this classification, most estuarine, coastal, and open-ocean waters are N-sufficient. To evaluate whether or not there is nutrient stress from too little or too much, it is probably necessary to look over sufficient time to be in essentially steady-state conditions. For instance, it has been suggested that in Southern Ocean waters, Redfield CNP ratios for plankton use were only obtained when averaging over the full vegetative season of the Austral summer (Hoppema and Goeyens, 1999). They suggested that the Redfield ratio was reached only because of nutrient-replete conditions.

Adding Silicon

The concept of the Redfield ratio has been extended to silicon for many studies of aquatic ecology. From laboratory culture studies, the average Si/N ratios for small and large diatom species is close to 1/1 (Brezinski, 1985). This would give an

overall Redfield ratio for CNPSiO of 106/16/1/16/–276 for balanced diatom growth. For a long time, it has been assumed that with deficiency of Si, phytoplankton populations will shift from diatom domination to that of other groups of algae. However, recent research would suggest a more absolute limitation of “healthy” ecosystem production by Si. In oceanic HNLC environments, it has been suggested that “new” production (that which is supported by upwelled NO_3) is reduced by Si limitation and thus export from pelagic primary production is controlled by Si availability. In coastal upwelling regions, it has been demonstrated that iron limitation will cause diatoms to increase the Si/N uptake ratio, depleting the water of Si, leading to secondary Si limitation. Clearly, Si is very important and can influence N response of the primary producers.

Comparative Si availability may be a major feature in the apparent eutrophication response seen in nearshore waters. In a recent 20-year comparison in the Bay of Brest, there was a large decrease in the Si/N ratio, “but, contrary to what has been observed in other coastal ecosystems, phytoplankton stocks have not increased” (LePape *et al.*, 1996). In light of the earlier discussion (see High Nutrients and Low Growth in Estuaries), maybe this is less of an exception than LePape *et al.* interpreted. In some cases, an increase in phytoplankton biomass is seen, but not always with a shift from diatoms, and rarely is there an increase in higher trophic level consumption of the primary production. In an extensive study of a very long term record for the Mississippi River outflow into the Gulf of Mexico, Rabalais *et al.* (1996) have shown a large decrease in the Si/N ratio accompanied with an increase in primary production but also an increase in the deposition of biogenic silica in the sediments underlying an increasingly large hypoxia region. The explanation is that with relative Si scarcity, diatoms that are in the plankton are not grazed efficiently, and they fall to subsurface waters and contribute to hypoxia.

Changing Nutrient Ratios

Probably most estuarine waters with impact from human activities show greatly changed N/Si as well as N/P ratios. In Table 2, average values for total dissolved inorganic nitrogen (NO_3 plus NH_4), PO_4 , and Si are shown for several nutrient-enriched estuaries. All of the examples show large increases in DIN and most have smaller proportional increases in P so that the N/P is usually considerably higher than would be the case without the anthropogenic influence. Since Si is not usually a byproduct of human activity, the Si concentration has not

changed much; there is probably a large natural variation depending upon the nature of the land drained for the estuary. A few systems probably have had significant decreases in Si due to decreased natural land erosion (dams, diked river banks); this is definitely the case with the Mississippi (Rabalais *et al.*, 1996). As a result, the N/Si ratio is much different from that prior to human impacts. Inverting this as Si/N, the pristine condition is about 10/1 and most of our nutrient-enriched systems show values of 1/1 or lower. This very likely has a serious negative impact on the primary production community. The importance of Si in relation to eutrophication has been recognized in the past, but usually only in relation to shift from diatom to flagellate flora (e.g., Officer and Ryther, 1980). With more recent information on interactive influences of Si, N, and Fe and on the fate of Si-limited diatom production, it is timely to reinvestigate the role of Si on eutrophication. While species responsible for HABs do not necessarily show greater affinity for nutrients in general, giving them ability to outcompete more “normal” phytoplankton like diatoms, it is probable that changing ratios of N and P to Si do favor some of the HAB flagellates (Smayda, 1990).

The large changes in N/P ratios are often not documented because of lack of complete nutrient records from long-range monitoring. In a data set from the Delaware Estuary, dissolved inorganic nitrogen has been measured regularly along the full axis of the estuary for over 35 years, but parameters for phosphorus measurements have varied over that period. Total P, a composite that includes dissolved organic and particulate phosphorus as well as PO_4 , has been measured consistently. A comparison of the N/P ratio change, based on the total P, over a 30-year period is shown in Figure 3. Recognizing that the majority of the P in the estuary today is PO_4 and that in the past PO_4 was probably a larger portion of the total, it is possible to view the N/P ratio as indicative of available P. This dramatic N/P ratio change is probably largely due to reduced input of detergent phosphorus and the same change has occurred in many U.S. estuaries (N. A. Jaworski, unpublished data, 1998). In the earlier situation, almost the entire estuary would appear to be replete in relation to P since the N/P was considerably below the Redfield ratio; in the more modern situation, N/P ratios are in the 30–60 range. However, it must be recognized that transport and availability of phosphorus in estuaries is a complex function that also involves geochemical influences. In the past 20 years, the P geochemical reactivity in the Delaware Estuary has changed due to increased pH and

Table 2 Approximate nutrient concentrations at the beginning of the salinity gradient for several nutrient-enriched estuaries^a

Estuary	DIN	PO_4	Si	N/Si/P	Reference
Scheldt	550	15	250	37/17/1	Zwolsman, 1994, 1999
Delaware	250	5	125	40/20/1	Sharp, unpublished data
Mississippi	114	7.7	108	15/14/1	Rabalais <i>et al.</i> , 1996

^aAverage concentrations of nutrients (in μM element) approximated from publications listed. Averages for total dissolved inorganic nitrogen (DIN), dissolved phosphorous (PO_4), and silicate (Si) and ratios normalized to P are listed. Values for pristine estuaries approximated from data for the Zaire and Magdalena River outflow systems.

Figure 3 N/P ratios for the Delaware Estuary using total dissolved inorganic nitrogen (DIN) versus total P from summer transects of the entire estuary in summers of 1967 and 1997 data from Delaware River Basin Commission routine monitoring.

Figure 4 Ratios from sampling along the distance axis of the Delaware Estuary in the spring from measurements of total dissolved inorganic nitrogen (N), P, Si, and Fe. The N/P ratio is generally in the 30–100 range over much of the estuary during much of the year and <16 only near the mouth of the bay. The N/Si ratio is generally between 1 and 2 during most of the year. The N/Fe ratio is in the 100–600 range except near the bay mouth, where it can become <100.

dissolved oxygen. As a result, the N/P ratio based on PO_4 only for average concentrations of the entire salinity gradient of the estuary has decreased in the past 20 years from about 90/1 to 40/1. More thorough analysis of many estuaries may show this dual trend of long-term decrease of N/P loading in an upper estuary but of more available dissolved PO_4 being delivered to the lower estuary. It is important to understand the full biogeochemical picture of estuarine phosphorus before accurate conclusions of nutrient impacts can be made.

In addition to long-term changes in nutrient ratios, there are large spatial changes in estuaries at any single time. **Figure 4** shows nutrient ratios along the full length of the Delaware Estuary from sampling in the spring. In the spring bloom condition in the estuary, NH_4 , PO_4 , and Si are exhausted from the mouth of the estuary moving up toward a strong-light-limiting turbidity maximum (Pennock and Sharp, 1994). The very high ratios of P and Si to N are due to the large excess NO_3 concentration of the river water as it is advected downstream. It is interesting to see that different regions of the estuary appear to have large differences in the nutrient that could be most limiting. Also, from this picture, it appears that Fe could be more limiting in the upper estuary than near the mouth of the bay. This greater proportional availability of Fe is a year-round occurrence. A noxious algal

Figure 5 Average ratios of N/P and N/Si for stations in the lower Delaware Bay for winter, spring, summer, and fall. During the spring (month 3), the maximum biomass for the entire estuary for the year is found in the lower bay. The maximum estuarine primary production is found in the summer in the lower bay.

group that has caused considerable international concern recently is responsible for brown tides. A recent analysis of brown tide occurrence suggests the macronutrient levels are not implicated but that Fe is.

In the Delaware Estuary, the area of the greatest phytoplankton production throughout the year is the lower bay (Pennock and Sharp, 1994). **Figure 5** shows macronutrient ratios for this region averaged on a seasonal basis. The maximum biomass is achieved in the spring bloom, where N/P and Si/N ratios indicate exhaustion of P and Si with residual NO_3 ; at this time, nutrient regeneration is minimal and there is also little herbivore grazing. Usually, the highest seasonal primary production is found in the summer. At this season, it would appear that grazing controls chlorophyll (Pennock and Sharp, 1994) and grazing is in balance with nutrient regeneration, which is sufficient to allow measurable NH_4 , PO_4 , and Si levels. At this season, the N/P ratio is close to Redfield and the Si/N ratio is sufficient to support healthy diatom growth although the flora is dominated by small flagellates. Acknowledging the caution of Hecky and Kilham (1988) that nutrient concentration does not equal nutrient utilization, we have demonstrated limitation in several ways (Pennock and Sharp, 1994). Looking at the entire estuary with highly nutrient enriched tidal freshwater region, a light-limited turbidity maximum in the oligohaline region, and clearer and nutrient-diluted lower bay, it would appear that the only time and place that near to Redfield ratio of nutrients is found is in the lower bay in the summer. We have performed preliminary simple mesocosm experiments and find that the CNPO fluxes approach Redfield stoichiometry only in the lower estuary in the summer (Sharp *et al.*, unpublished data). In the lower estuary in the spring bloom, close to Redfield ratios of NPSiO occur but there appears to be an accumulation of C with the biomass accumulation. In the nutrient-rich upper estuary, nothing close to expected stoichiometry is seen. Further research on this anomalous stoichiometry is currently underway in my laboratory.

Contaminants and Stress

The lack of high growth rates of estuarine and coastal phytoplankton in the presence of high nutrient concentrations leads to the suggestion that anthropogenic contaminants,

other than nutrients, may have an influence on ecosystem response. The MERL research facility mentioned earlier has extensive and expensive controls of the large tanks for the studies. A number of excellent experiments have been carried out also in less sophisticated smaller mesocosms in other estuarine areas. One interesting study done in Chesapeake Bay mesocosms over several seasons showed that nutrient enrichment by N and P caused growth of "beneficial" diatom species over flagellates (Sanders *et al.*, 1987). A conclusion of that study was that many other factors probably control community dynamics. As discussed earlier, the lack of predation is often a factor in noxious algal species proliferation. Also discussed earlier is the suggestion that ratios of nutrients may be more important than quantities in causing eutrophication responses. It is possible also that contaminants cause stress to the "desirable" algal species and to grazers that would otherwise consume the primary production.

Most estuaries with large anthropogenic influences have had chronic exposure to many chemicals in addition to nutrients. Chronic exposure to arsenic appeared to cause reductions in phytoplankton cell size with less trophic transfer while chronic exposure to silver resulted in essentially the opposite. Thus, arsenic would appear to be partially responsible for eutrophication response. Many estuaries also have frequent or continuous inputs of chlorination byproducts which must have a selected influence. Sanders (1984) showed that one diatom and a chrysophyte would not grow in aged chlorinated water (with levels below detection for total residual chlorine) where a more resistant flagellate would grow. This result would also favor species other than "normal" with potential to decrease trophic transfer.

Paerl (1998) has illustrated positive and negative interactions and feedback from nutrient loading, emphasizing that negative influences on grazing can increase the impact of primary production. In lakes, it has been shown that combinations of nutrient additions and zooplankton size can have major influence on phytoplankton sizes and thus on trophic transfer. The variability in nutrient and trace metal impacts on phytoplankton, bacterioplankton, heterotrophic protozoa, copepods, fish, and benthos caused variable trophodynamic responses in estuarine mesocosm experiments (Breitburg *et al.*, 1999). These authors concluded that trace elements may mask the response of high nutrient loadings in eutrophic systems. In lake studies, N, P, and C had different controlling effects on zooplankton, phytoplankton, and bacterioplankton, with variable responses in different seasons.

An overall conclusion is that eutrophication as a stress in estuarine and coastal marine environments is not a simple cause-and-effect phenomenon. Nutrient enrichment elicits complex and variable responses from the phytoplankton, bacterioplankton, and protozoa that make up the primary producer community. Increased nutrient concentrations and loadings may cause an overall increase in phytoplankton biomass, but not invariably from higher growth rates. Shifts in dominant species and shunts through the microbial loop may decrease the trophic transfer to higher metazoan levels. The biodiversity of the aquatic community may allow some resilience to the system (Patrick, 1988), but ultimately changes in the diversity are probably more important than a direct response to increased levels of nutrients.

Glossary

Biogeochemistry The discipline which studies biotic controls on the chemistry of the environment and geochemical controls on the structure and function of ecosystems.

Deposition The delivery of material inputs to the earth's surface from the atmosphere.

Eutrophic High in production or species typical of high-production environments.

Mineralization The conversion of an element from an organically bound form to an inorganic form.

Nitrification The oxidation of ammonia to nitrite and nitrate by bacteria.

Nitrogen fixation The reduction of atmospheric N_2 to ammonia or other organic or inorganic compounds by bacteria, lightning, or photochemistry.

Nitrogen saturation Nitrogen supply in excess of the capacity of the ecosystem to retain nitrogen.

Nutrient limitation The addition of a nutrient or nutrients to an ecosystem causes an increase in net primary production.

Oligotrophic Low in production or species typical of low-production environments.

Opportunistic species Species typical of transient, unstable, unpredictable, frequently disturbed, or periodically extreme environments, usually having strong dispersal abilities and faster growth, smaller size, and shorter life spans than potential competitors.

Introduction

Nitrogen is an essential element for life and it frequently controls productivity and community structure in both terrestrial and aquatic ecosystems. During the past several decades, human activity has changed the nitrogen cycle more than any other element cycle, resulting in many deleterious environmental changes, including decreased biotic diversity.

An Overview of the Nitrogen Cycle and its Ecological Importance

Nitrogen (N) is an essential element for all life on Earth, a required component of deoxyribonucleic acid (DNA), all proteins (including enzymes), chlorophyll, and many other critical constituents of biological structure and function. More than 99% of nitrogen on Earth is present as molecular N_2 , with most of this in the atmosphere and some dissolved as a gas in the oceans. However, most organisms cannot use the relatively inert N_2 molecule. Paradoxically, molecular N_2 is not a thermodynamically stable compound in the presence of oxygen, but these two gases coexist and comprise virtually all the atmosphere. The nitrogen in N_2 becomes biologically available only when the N–N bond is broken and nitrogen is combined with other elements to form compounds such as ammonium (NH_4^+) and nitrate (NO_3^-) in a process called nitrogen fixation. Prior to the massive alteration in the global nitrogen cycle by human activity, small amounts of nitrogen were fixed by lightning and by volcanic activity, but the vast majority of nitrogen fixed on Earth each year (more than 95%) was fixed by bacteria. Not all bacteria are capable of fixing nitrogen, although the ability is fairly widespread among diverse groups of bacteria including cyanobacteria, nonoxygenic

photosynthetic bacteria (such as purple sulfur bacteria), and many classes of heterotrophic bacteria. No other organisms are capable of nitrogen fixation, although many plants, lichens, mosses, and some animals have bacterial symbionts which fix nitrogen. These plants with symbiotic nitrogen-fixing bacteria include many species of trees (such as alders in the temperate zone and many species in moist tropical forests) and many agricultural crops, including alfalfa, peas, peanuts, soybeans, and rice. Plants with symbiotic nitrogen-fixing bacteria are often loosely called 'nitrogen fixers,' although it is always the bacteria that are actually fixing nitrogen.

For most of the history of life on Earth, the demand by plants for biologically available forms of nitrogen such as nitrate and ammonium has been greater than the rate of supply by nitrogen fixation. Consequently, nitrogen limits the primary productivity in many ecosystems, and when more biologically available nitrogen is added to these systems plant production increases. This relative lack of availability of nitrogen globally has also been a major factor shaping the evolution of life and structuring the communities in many different types of ecosystems, both terrestrial and aquatic.

The general patterns which relate productivity and diversity in ecosystems are well established. In aquatic ecosystems, species diversity declines with increasing productivity, and diversity is greatest in systems of very low productivity, such as oligotrophic lakes and areas of low productivity in the oceans in which colimitation by multiple nutrients (including nitrogen) may be common. In terrestrial ecosystems, the greatest diversity of plant species usually occurs in sites of intermediate fertility and productivity. In sites of very low fertility, the resources can support only a few viable populations able to tolerate the severe conditions. In very high fertility sites, competition intensifies and may shift from competition for nutrients to the more asymmetrical competition for light or space, resulting in dominance by a few species. For both

aquatic and terrestrial systems, when nitrogen is limiting production, it is also influencing diversity.

The importance of nitrogen as a factor limiting productivity and regulating community structure varies among the earth's ecosystems, with nitrogen being of paramount importance in some systems and not limiting at all in others. Although there are exceptions, among terrestrial ecosystems nitrogen availability generally controls production in temperate forests, boreal forests, arctic and alpine tundra systems, temperate and tropical grasslands, and agroecosystems. However, phosphorus or other elements – and not nitrogen – tend to limit production in most tropical forests if any element is limiting, except in forests on very young soils (less than a few tens of thousands year old), where nitrogen is commonly limiting. Among aquatic ecosystems, nitrogen limits production in most estuaries and coastal seas of the temperate zone and perhaps in some tropical seas, although these are sometimes phosphorus limited. Nitrogen with phosphorus as a colimiting element may regulate production in much of the oceans away from shore as well. However, phosphorus is generally more important in regulating production in freshwater lakes, at least in moderately or highly productive lakes in the temperate zone.

These patterns of nutrient limitation are the result of many processes which regulate the availability of nitrogen in comparison to other elements essential for plant growth. For terrestrial ecosystems, one important aspect is the change in phosphorus biogeochemistry as soils develop over geological time. In a geologically young soil, the initial amount of phosphorus is often high, but as the soil is weathered this phosphorus is exported from the system or stored in mineral forms which make the phosphorus biologically unavailable. In the temperate zone, soils are often young due to glaciation within approximately the past 20,000 years. However, many tropical soils are extremely old and highly weathered and therefore have very low availabilities of phosphorus. This is one factor which tends to make tropical forests phosphorus limited and temperate forests nitrogen limited.

Differences in nitrogen processes among systems are also important in determining which element is most limiting to primary productivity. Nitrogen fixation is one critically important process, and it is much more prevalent and occurs at higher rates in tropical forests than in temperate forests. This contributes to the greater tendency for nitrogen limitation in temperate forests. An interesting paradox is that nitrogen fixation does not alleviate nitrogen shortages in temperate forests and thereby alleviate nitrogen limitation. Why should any ecosystem be nitrogen limited if nitrogen fixation could provide sufficient inputs? Why is nitrogen fixation in temperate forests so much less than that in tropical forests? The reasons for the relatively low rates of nitrogen input to nitrogen-limited temperate forests remain poorly known and are an active area of research. A similar paradox occurs in aquatic ecosystems. One of the reasons that freshwater lakes tend to be limited by phosphorus is that planktonic cyanobacteria in these systems can often fix sufficient nitrogen to alleviate any potential nitrogen limitation. In contrast, nitrogen fixation by planktonic cyanobacteria rarely occurs in even strongly nitrogen-limited estuaries. The relative lack of nitrogen fixation in estuaries is probably due to an interaction of two

factors: trace metals that are required for the process of nitrogen fixation (molybdenum and iron) are less available in estuaries than in lakes, slowing the potential growth rate of nitrogen-fixing organisms, and this slow growth rate makes cyanobacteria highly susceptible to grazing mortality by zooplankton and benthic animals.

Nitrogen fixation is only one process affecting nitrogen availability in an ecosystem. Also important are the processes which regulate the loss of nitrogen from the system and the input of biologically available forms of nitrogen from neighboring ecosystems and from the atmosphere. A brief summary of the nitrogen cycle illustrates the complexity. The nitrogen that is fixed accumulates over time in both the living and nonliving components of ecosystems and is transported and transformed by numerous processes (**Figure 1**). Ammonium and nitrate are taken up by plants as well as by microorganisms and converted to organic nitrogen compounds. This organic nitrogen is cycled through food webs but also accumulates in soils, water, and sediments as organisms die, excrete matter, or drop tissues such as the fall of leaves from trees. Much of the nitrogen in this nonliving organic matter is not readily available for use by organisms, but microbial decomposition of the organic matter releases ammonium, which can then be oxidized to nitrate by bacteria. Both nitrate and ammonium are highly soluble in water, but the negatively charged nitrate ion is more easily leached from soil and transported to aquatic ecosystems. In ecosystems where oxygen concentrations are low (such as in the sediments of wetlands, lakes, and estuaries), the nitrogen in nitrate can be converted back to molecular N_2 (or the slightly oxidized gas N_2O , which is a very powerful greenhouse gas) by bacteria in a process called denitrification. Also, in soils and waters where the pH is sufficiently high to favor the dissociation of ammonium to ammonia (NH_3), nitrogen can be lost to the atmosphere as ammonia gas. Fires can also volatilize both ammonia and oxidized gases of nitrogen (such as NO and N_2O) to the atmosphere. Most of these forms of nitrogen are redeposited from the atmosphere onto the earth's surface in precipitation or as dry deposition.

Human Impacts on the Nitrogen Cycle

Human activity has altered the nitrogen cycle globally more than that of any other element cycle, and much of the change has occurred during the past 50 years. The increase in carbon dioxide and other greenhouse gases in the atmosphere is, appropriately, a cause of widespread alarm, but the rate at which humans have altered nitrogen availability on land is even greater. As recently as 40–50 years ago, the major source of fixed nitrogen was still natural biological nitrogen fixation, but today more nitrogen is fixed through human activities than by all nitrogen fixation in natural terrestrial ecosystems on Earth (**Figure 2**). The greatest change has been the widespread use of synthetic nitrogen fertilizer, and the production of such fertilizer today accounts for more than half of the total amount of nitrogen fixed by all human activities. The process for making nitrogen fertilizer from atmospheric N_2 was invented in the early twentieth century, but such fertilizer was not widely used until the 1950s. The rate of use has increased

Figure 1 Simplified diagram of the nitrogen cycle. Reproduced with permission from Cunningham and Saigo (1995).

steadily since then, with only a modest interruption caused by the collapse of the former Soviet Union and the disruption of agriculture in Russia and eastern Europe in the early 1990s. Most of the synthetic nitrogen fertilizer that has ever been used on the planet has been used during the past 25 years.

The synthesis of inorganic fertilizer accounts for 60% or more of the total amount of nitrogen fixed globally through human activities, with the rest coming primarily from the production of nitrogen-fixing crops in agriculture and from the combustion of fossil fuels. Fossil fuel combustion not only releases nitrogen from geological storage in the fuel but more importantly catalyzes the reaction of O_2 and N_2 as fossil fuels are burned. This nitrogen is released as oxidized nitrogen gases, generically referred to as NO_x , which are subsequently deposited onto the earth's surface in precipitation or dry deposition. Overall, human fixation of nitrogen (including the production of fertilizer, combustion of fossil fuel, and production of nitrogen-fixing agricultural crops) increased globally approximately three- or fourfold between 1960 and 2010 and continues to increase. By the year 2000, human activities made fixed nitrogen available at a rate of approximately 170 Tg year^{-1} , or more than $1\text{ g N m}^{-2}\text{ year}^{-1}$ when averaged over the entire land surface of the earth.

Nitrogen from human sources can travel for fairly long distances in the environment. For instance, much of the nitrogen deposited from the atmosphere in the northeastern

USA comes from the combustion of fossil fuels in the Midwest, and the majority of nitrogen flowing down the Mississippi River and causing eutrophication in the Gulf of Mexico originates from agricultural sources in Illinois, Iowa, Indiana, Minnesota, and Wisconsin. Of the nitrogen fertilizer applied to agricultural fields, some leaches into ground water and surface water and affects downstream ecosystems; on average in the USA, approximately 20% of nitrogen fertilizer is thus exported from agroecosystems, although this percentage ranges from only 3% to 80% depending on the soil type, climate, and agricultural practices. Nitrogen from agricultural sources also gets volatilized into the atmosphere and thereby redistributed onto nonagricultural lands, including forests. Some of this nitrogen is volatilized directly from the agricultural fields, as both ammonia and NO_x , with the flux of NO_x being particularly important in tropical areas. Also of importance is the volatilization of ammonia to the atmosphere from animal wastes. In developed countries, approximately half of the nitrogen used as fertilizer is exported from the field in crop harvest, on average, with most of these crops being fed to livestock and poultry. Much of the nitrogen in these feedstocks ends up in the animal wastes, with a high percentage being volatilized. The total flux of such volatilization in the USA is almost as large as the leaching of nitrogen directly from fertilized fields. Increasingly over the past several decades, crops may be transported hundreds of

Figure 2 Anthropogenic fixation of nitrogen compared to the range of estimates of natural biological fixation on land. Policy Responses, the Millennium Ecosystem Assessment. Washington, DC: Island Press.

kilometers or more to animal feedlot operations, making it unlikely that the animal wastes are ever transported back to the fields, thereby compounding nitrogen pollution problems. The steady input of new synthetic nitrogen fertilizers makes such practices possible.

Reactive nitrogen compounds are usually transported for only a few hundred kilometers to at most approximately 1000 km through the atmosphere, and rivers and ocean currents transport biologically available forms of nitrogen on the same sort of spatial scales. As a result, the alteration of the nitrogen cycle is not uniform over the earth, and the greatest changes are concentrated in the areas of greatest population density and greatest agricultural production. Generally, the largest changes have occurred in the northern temperate zone. The tropics have seen less change through the twentieth century, but that has been changing over the past decade. Most terrestrial ecosystems and most coastal marine ecosystems in the temperate zone are nitrogen limited, and therefore, the acceleration of nitrogen cycling in the northern temperate zone has had a great impact. Current deposition of nitrogen from the atmosphere onto the landmasses of the Northern Hemisphere temperate zone is almost seven times more than the preindustrial deposition, and in some regions, such as the northeastern USA, Western Europe, and east Asia, the increase has been far greater. The natural rate of biological nitrogen fixation in European watersheds of the North Sea and in the northeastern USA is approximately $0.5 \text{ g N m}^{-2} \text{ year}^{-1}$ or less and human activity has increased nitrogen input to the watersheds of the North Sea to $7.5 \text{ g N m}^{-2} \text{ year}^{-1}$ and in the northeastern USA to $4.1 \text{ g N m}^{-2} \text{ year}^{-1}$. The export of nitrogen in major rivers to coastal oceans in both Europe and North America is closely related to the increased inputs of

nitrogen to the basins from human activities (Figure 3). Downstream transport of nitrogen to estuaries and coastal oceans has increased up to 20-fold in some areas such as the North Sea. Figure 4 shows the spatial pattern of these nitrogen inputs from human activity across the lower 48 states of the USA, which drive the increased nitrogen export downstream. Note in particular the high levels of net anthropogenic nitrogen inputs in the corn belt of the upper mid-west, and hot spots along the east and west coasts of the USA associated with concentrated animal agricultural operations and high density of human populations.

The rate at which human activity has accelerated nitrogen cycling varies widely among regions of the world. Globally, the use of synthetic nitrogen fertilizer continues to increase, but in the USA and many other developed countries fertilizer use has changed little since 1980, and fertilizer use has actually fallen in western Europe and even more so in the former Soviet Union. In China, however, the use of synthetic nitrogen fertilizer has increased 2.5-fold from 1980 to 2000 and continues to increase at a rate of over 4% per year. For the past decade or two, China has been using one-third of all inorganic nitrogen fertilizer produced globally. The acceleration of nitrogen use in developing countries has allowed major increases in food production and has greatly reduced starvation, but the environmental consequences are becoming increasingly apparent.

Effects of Nitrogen on Biodiversity

Human acceleration of the nitrogen cycle has tremendous implications for biodiversity at all scales, from the genome to

Figure 3 Export of nitrogen from rivers in both North America and Europe is strongly correlated with the net nitrogen inputs to the watersheds (NANI) caused by human activities, especially agriculture and combustion of fossil fuels, on both a linear and log-log scales. the globe. Reduced genetic diversity within species exposed to high levels of nitrogen deposition has been documented in tree species, soil mycorrhizae, and *Rhizobium spp.* in beans. Changes in species composition and reductions in species diversity are obvious and widespread. Declining ecosystem and landscape diversity are becoming evident. In return, changes in biodiversity influence nitrogen dynamics and processes, creating complex nonlinear interactions and feedbacks between nitrogen cycling and biodiversity. Nitrogen enrichment can reduce biodiversity by several mechanisms including acidifying soil and water as well as increasing the growth and dominance of a few particularly responsive species in nitrogen-limited ecosystems.

Effects of Eutrophication on Biodiversity

The substantial increase in nitrogen inputs to nitrogen-limited ecosystems as a result of human activities alters species composition (which species are present) and decreases species diversity (the number of species and the evenness of their relative abundance). A few fast-growing opportunistic species, with greater ability to take advantage of the increased availability of nitrogen to produce additional biomass, usually become dominant in fertilized ecosystems, while the species characteristic of less fertile environments (oligotrophic species) decline and disappear. Often, a relatively diverse flora, including rare endemic plants, characteristic of an oligotrophic ecosystem is replaced by a more productive, but less diverse flora dominated by a few common weedy species, normally found in mesotrophic or eutrophic sites. Usually, invasive pest plants respond strongly to increased availability of nitrogen, and generally eutrophication facilitates the spread of introduced and native pest plants. As plant species are lost from an ecosystem, additional animal species associated with those plants may be lost as well, further decreasing species diversity. The conversion of whole ecosystems from oligotrophic to eutrophic and the disappearance of entire types of ecosystems encompass the extinction of large groups of species, not just a few particularly vulnerable endangered species, and reduce biodiversity on the local, landscape, and regional scale.

The decrease in species diversity caused by the eutrophication of terrestrial and aquatic ecosystems has been observed consistently across a wide variety of nitrogen-limited ecosystems. However, the speed and magnitude of the effects of increased inputs of nitrogen on biodiversity depend on the characteristics and history of the affected ecosystem. The mobilization and redistribution of nitrogen by human activity can cause local areas of nitrogen depletion, even though the amount of fixed nitrogen has increased overall. Semiarid and arid lands and unfertilized agricultural and overgrazed systems are particularly susceptible to the loss of nitrogen-containing topsoil. In some cases, nitrogen depletion can threaten biodiversity much as nitrogen addition reduces biodiversity. In very unproductive ecosystems, the addition of nitrogen may cause an initial, usually transient, increase in species diversity by allowing the invasion of native species from more fertile sites in the same region or exotic species introduced from other regions. Even when species diversity remains elevated,

often the oligotrophic species are lost from the ecosystem, contributing to a regional decline in species diversity. The effects of nitrogen enrichment may be delayed in systems which are severely nitrogen limited due to previous depletion of nitrogen by fire or human activities, such as forest clearing or timber harvesting.

Enrichment of grasslands with nitrogen causes productivity increases in a few dominant grasses and severe declines in species diversity, as shown by experiments in North America, Australia, and Europe (Figure 5). In one long-term study of fertilizer addition to a grassland in England, species diversity was reduced by more than fivefold. Oligotrophic, calcareous grasslands in Europe, with high biodiversity and many endemic species, are particularly sensitive to species loss due to eutrophication and most sites have already experienced changes in species composition. Fertilization and increased productivity decrease species diversity by allowing fast growing, tall plants to shade competitors and sometimes by increasing production of litter which prevents the establishment of seedlings. Increased availability of nitrogen suppresses nitrogen-fixing plant species and consequently many of the forbs lost from eutrophied grasslands and heaths are nitrogen-fixing species. The mechanisms by which nitrogen enrichment reduces biodiversity may be quite specific to the circumstances of each ecosystem. For example, when nitrogen was added to fertile wet and infertile dry sedge meadows in Colorado, diversity declined in the wet meadow but not in the dry meadow. In the infertile dry meadow, nitrogen additions released rare species from nitrogen limitation, increasing the evenness of species abundances, but in the more fertile wet meadow the already dominant species increased in abundance, suppressing subordinate species. Nitrogen inputs affect not only plant diversity but also the diversity of the animal community. It has recently been suggested that nitrogen deposition near San Francisco may be a contributing factor leading to the decline of a threatened, endemic butterfly.

Figure 5 Species richness of plants in grasslands across Europe as a function of nitrogen added in a variety of experiments. Reprinted from Figure 2 in Bobbink R, Hicks K, Galloway J, *et al.* (2010) Global assessment of nitrogen deposition effects on terrestrial plant diversity: A synthesis. *Ecological Applications* 20: 30–59, with permission from ESA.

In many ecosystems, moderate levels of grazing – within the range typical of the evolutionary history of the system and plants – tend to increase plant species diversity. Grazing can interact with nitrogen availability to affect diversity, and ungrazed or lightly grazed grasslands are more susceptible to decreases in biodiversity caused by nitrogen enrichment because heavy grazing usually suppresses the dominant grass species stimulated by nitrogen. Nitrogen enrichment usually reduces the spatial heterogeneity of nitrogen and therefore reduces the potential for different species to coexist using microsites with different availabilities of nitrogen. Grazing redistributes nitrogen and usually increases the spatial heterogeneity and temporal variability of nitrogen availability, contributing to the maintenance of biodiversity. However, when fertilization increases productivity sufficiently to support greatly increased grazing, grazing-intolerant plant species may be lost from the ecosystem.

Diversity in forests is also affected by nitrogen additions, as has been particularly well studied in parts of Europe in which nitrogen deposition from the atmosphere is high. In both deciduous (the Netherlands and France) and coniferous forest (Sweden and Finland), nitrogen enrichment has caused shifts in the species composition of the understory, favoring opportunistic species with high nitrogen requirements and reducing biodiversity of lichens, mosses, and vascular plants. Increased nitrogen deposition has caused weakened tree trunks, decreased frost hardiness, and increased pest outbreaks in some forests. After many years of high nitrogen deposition, some forests of Western Europe have become 'nitrogen saturated,' unable to store additional nitrogen in soil or vegetation. In nitrogen-saturated ecosystems, continuing nitrogen inputs are balanced by comparable nitrogen outputs, accelerating both the eutrophication of downstream waters and the loss of other essential elements from the forest.

In the Netherlands, the high population density, with accompanying industry and vehicles, is combined with intensive livestock production to generate perhaps the highest rates of nitrogen deposition in the world. More than 35% of oligotrophic, diverse heathlands in the Netherlands have suffered nitrogen accumulation, invasion by grasses, and reduced diversity. In dry heathlands, this nitrogen fertilization has stimulated outbreaks of the heather beetle, accelerating the conversion to grassland. Some heaths have been completely converted to much less diverse grasslands and forest, reducing the landscape and regional diversity as well as the diversity within the heathlands. The beginnings of similar eutrophication of heathlands have been observed in Norway and in the UK.

Estuaries and other coastal waters receive a variety of inputs from human activities. Perhaps the greatest pollution problem, however, is the eutrophication that results from increased nitrogen inputs. Eutrophication of coastal marine ecosystems frequently results in hypoxia (the depletion of dissolved oxygen) or anoxia (the absence of dissolved oxygen), both of which result not only in fish kills and the loss of other biotic resources but also in sharp decreases in biotic diversity. Hypoxia has severe effects on the diversity and abundance of benthic species, shifting dominance from large, long-lived, less mobile species to smaller, mobile, opportunistic, short-lived species. Frequent hypoxia may prevent

successional development beyond the early colonizing community. The loss of burrowing benthic organisms that irrigate and oxygenate the sediments may strongly influence biogeochemical processes such as phosphorus adsorption and nitrification and denitrification, which can feed back to influence diversity. Increased nitrogen inputs have caused increased hypoxia and anoxia in Chesapeake Bay, the Baltic Sea, the Black Sea, Long Island Sound, Florida Bay and the Florida Keys, the northern Adriatic Sea, and many other areas globally. The hypoxic 'dead zone' in the northern Gulf of Mexico increased from 9500 km² when first reported in 1991 to well over 20,000 km² in most years since 1999 and is the direct result of nitrogen inputs coming down the Mississippi River.

Not all the effects of eutrophication on biodiversity are due to hypoxia and anoxia. Nutrient enrichment also leads directly to changes in the composition of the phytoplankton community, and these can cascade up the food web generally leading to lowered diversity at each trophic level. Eutrophication of coastal waters is often accompanied by a decrease in silica availability, due both to increased sedimentation of silica within estuaries and to trapping of silica in upstream, eutrophic fresh waters. Since silica is required by diatoms, but not by other types of phytoplankton, eutrophication often results in a relative loss of diatoms from the community. A fourfold increase in the relative inputs of nitrogen compared to silica along the German coast during the past few decades was accompanied by a 10-fold decrease in diatoms and a comparable increase in flagellates, which are less conducive to supporting food webs leading to commercially valuable fisheries. Decreased silica availability and the concomitant loss of diatoms may also be responsible, at least in part, for the increased frequency of occurrence and duration of blooms of harmful algae that seem to accompany coastal eutrophication. Harmful algal blooms ('red tides,' 'brown tides,' and 'green tides') can kill animals, such as sea lions, far up the food chain. The resulting loss of important top predators such as sea otters can cascade back down the food chain, altering species composition and reducing biodiversity.

Coastal systems that are both high in biodiversity and severely affected by eutrophication are seagrass beds and coral reefs. Temperate seagrass beds are usually nitrogen limited, whereas tropical seagrass beds and coral reefs are often phosphorus limited. However, even these tropical systems probably become nitrogen limited once eutrophication begins, and therefore additional inputs of nitrogen can cause immense harm. For the seagrasses, eutrophication leads to an immediate loss in diversity and can lead to a complete loss of the grasses due to shading by the increased biomass of phytoplankton in the water column, shading by mats of opportunistic species of macroalgae, or an accumulation of toxic decomposition products in the sediments. Eutrophic shallow estuaries and lagoons with large accumulations of macroalgae may experience frequent episodic oxygen depletion, further reducing biodiversity. Seagrasses provide food and shelter for a rich and diverse fauna, and reduced seagrass depth distribution or replacement by macroalgal blooms can result in marked declines in the abundance and biodiversity of the associated fauna.

Coral reefs occur in the oligotrophic shallow waters of the tropics, support extraordinary biodiversity, and are extremely

sensitive to damage from eutrophication. The biodiversity of coral reefs declines dramatically with eutrophication from nitrogen inputs, especially when species-poor turf algae or macroalgae communities overgrow and replace corals and coralline algae. Nutrient enrichment disrupts the coral-zooxanthellae symbiosis, inhibiting calcification and contributing to increased coral 'bleaching' (loss of zooxanthellae). Increased phytoplankton biomass and production increase turbidity and sedimentation. The decreased quality and quantity of light penetrating to the corals slow growth and reduce the maximum depth at which the corals can survive, reducing the available habitat. Algal blooms can cause hypoxia, decreasing the biodiversity of reef organisms through mortality and reduced habitat quality. Also, eutrophication can damage reefs indirectly by increasing predation on corals, facilitating the expansion of opportunistic filter feeders, and reducing the recruitment of corals.

Effects of Acidification by Nitrogen on Biodiversity

A variety of oxidized nitrogen compounds (NO_x) are released into the atmosphere in the exhaust of vehicles, electric power plants, and other fossil fuel combustion. Oxides of nitrogen are also released from soils and burning vegetation. In the presence of sunlight, NO_x catalyzes the formation of photochemical (or brown) smog and reacts with oxygen and hydrocarbons from automobile exhausts to form ozone, an air pollutant damaging to many plant species. In the atmosphere, NO_x reacts to form nitric acid, one of two major components of acid rain (the other is sulfuric acid).

At least 70% of global ammonia (NH_3) emissions are caused by humans, mostly by volatilization from fertilized fields, animal wastes, and forest burning. In the atmosphere, NH_3 neutralizes some of the acidity in aerosols, cloud water, and precipitation. However, once deposited on the earth's surface, ammonium (NH_4^+) is taken up by plants or converted to nitrite (NO_2^-) and then nitrate (NO_3^-) by bacteria. These processes of biological uptake and nitrification release hydrogen ions, acidifying the soil and downstream aquatic systems. Other processes, such as increased biological nitrogen fixation or increased rates of decomposition, which increase the amount of ammonium in the soil, also contribute to acidification.

As nitrogen inputs to ecosystems increase and the capacity of the ecosystems to retain nitrogen is lessened, ecosystems begin to release increasing amounts of NO_3^- . When the negatively charged ion leaves the ecosystem, it carries with it positively charged base cations, such as Ca^{2+} , Mg^{2+} , and K^+ . These elements are essential plant nutrients and their removal can deplete soil fertility and cause serious nutrient imbalances which are detrimental to plants. As the other soil cations are depleted, toxic Al^{3+} is mobilized. Soils with low capacity to neutralize or buffer the increased acidity from nitrogen and acid deposition are especially sensitive to acidification. Increased acidification may be the major impact of increased nitrogen deposition in ecosystems which are not nitrogen limited, such as many tropical forests and most temperate lakes, or are already nitrogen saturated, such as some temperate forests.

Until recently, most of the impacts of humans on nitrogen dynamics were focused in the temperate zone, but industrial and agricultural practices are changing rapidly in the tropics, where most of the earth's biodiversity resides and for which our ecological knowledge is rudimentary. By 2020, approximately two-thirds of the global application of industrial nitrogen fertilizer and energy-related nitrogen inputs will occur in the tropics and subtropics. The majority of tropical forests are probably not nitrogen limited and nitrogen enrichment will likely have little direct effect on plant production but instead will substantially increase the output of dissolved and gaseous nitrogen from these ecosystems. The acid soils of the tropics may be particularly susceptible to further acidification, depletion of base cations, decreased availability of plant nutrients, and release of toxic Al^{3+} , all possibly reducing productivity and biodiversity.

The effects of acidification on sensitive terrestrial and aquatic ecosystems are clear and severe. Increasing acidity of thousands of lakes and streams and the loss of fish and amphibian populations have been documented in Scandinavia and eastern North America. Experimental acidification of an entire Canadian lake eliminated shrimp, minnow, and crayfish species, all important food sources for the lake trout, which subsequently ceased reproduction. Increased nitrogen deposition has been implicated in the dieback of poorly buffered high-elevation forests in Europe and damage to high-elevation red spruce and fir forests in the northeastern USA. Acid deposition causes direct damage to trees by leaching base cations from leaves. Exposure to acid fog and cloud water, usually much more acidic than rain, increases sensitivity to frost damage. Acidification of forest soils causes nutrient imbalances, cation loss, aluminum toxicity, reduced growth rates, and increased mortality in trees. The diversity of lichens is greatly reduced by acidic deposition and the species composition of vascular plants, soil animals, and microbes shifts toward a less diverse community of acid-tolerant species. Acidification of grasslands and heathlands is widespread in Europe and results in decreased plant diversity when acid-tolerant species replace the species typical of less acid soils.

Terrestrial and aquatic ecosystems subjected to increased inputs of nitrogen often experience both eutrophication and acidification. The combined effects on biodiversity may be independent, additive, or synergistic depending on the characteristics of the ecosystem, but interactions between eutrophication and acidification are common. For example, nitrogen saturation increases the loss of base cations from the soil, accelerating acidification, while acidification strips base cations from plants, increasing the severity of the nutrient imbalances caused by eutrophication.

Effects of Biodiversity on Nitrogen Dynamics

The global biodiversity crisis has prompted increased concern for the possible effects of extinction of native species and introduction of invasive species on ecosystem function and the provision of ecosystem services essential to humans. The effects of biodiversity on nitrogen dynamics have not been studied as thoroughly as the converse effects of nitrogen on biodiversity, but there are numerous examples of significant

effects of particular species or functional groups of species on ecosystem processes, including nitrogen dynamics. There are far fewer examples of the effects of species diversity (the number and relative abundance of species), independent of the species composition (specific identity of the species present), on ecosystem processes such as primary production and biogeochemistry.

At larger scales, the effects of ecosystem and landscape diversity on nitrogen dynamics vary with the specific ecosystems and their spatial relationships. Ecosystems which capture or accumulate nitrogen, such as riparian zones bordering farm fields or wetlands upstream of estuaries, can be very important in controlling the transport and downstream impact of nitrogen. Declines in biodiversity associated with the fragmentation and homogenization of landscapes, land clearing, and development may increase the magnitude and variability of exports of nitrogen from the disturbed or converted ecosystems.

Particular species sometimes play unique or dominant roles in ecosystems and the introduction or elimination of these key species can dramatically alter the structure and function of particular ecosystems. For example, the introduction of a nitrogen-fixing tree to a Hawaiian ecosystem which contained no other nitrogen-fixing trees rapidly increased the availability of nitrogen and led to other changes in species composition of the vegetation. Burrowing animals, such as pocket gophers or prairie dogs, increase the rate of mineralization of nitrogen and increase the heterogeneity and availability of nitrogen. In many grasslands, grazers accelerate the rate of nitrogen cycling and influence the distribution and availability of nitrogen as well as the species composition of the plant community. In the boreal forest, in contrast, selective browsing by moose on deciduous trees containing more readily mineralized nitrogen slows nitrogen cycling and speeds succession toward coniferous forest. Addition or removal of whole groups of species that are performing the same functional role ('functional group') has effects similar to removing or adding a single species which is performing a unique function (a functional group with one member). For example, functional groups including nitrogen fixers, leaf-chewing insects in streams, and early spring ephemeral plants of the forest understory all have significant effects on nitrogen dynamics. To date, most of the investigations of the effects of diversity on ecosystem processes have focused on the diversity within groups of primary producers, usually herbaceous plants, but the effects of diversity at other trophic or organizational levels (consumers, predators, microbes, soil invertebrates, or whole ecosystems) may differ from the effects on primary producers. The influence of species or functional group diversity on ecosystem processes may differ for each functional group.

Undoubtedly, the idiosyncratic traits of individual species can influence nitrogen dynamics, but species also share many similar characteristics, compete for some of the same limited resources, and carry out some of the same ecosystem functions. If species are very similar, then redundancy is high and the removal of a single species would have little impact on ecosystem function. Alternatively, if species are very different (idiosyncratic) and there is little niche overlap (rather, niche differentiation), then the removal of a particular species would

have a greater impact on ecosystem function. As the number of species increases, the probability of including an extremely effective dominant species in the more diverse community increases. This simple 'sampling effect' is a result of changing species composition which occurs simultaneously with increasing species diversity.

Spatial and temporal variability in resource availability and environmental conditions are characteristic of most ecosystems; therefore, there are many ways in which species might differ in their use of resources and the environment. One species may be capable of symbiotic nitrogen fixation, whereas another can use organic nitrogen and another prefers NO_3^- or NH_4^+ . One species may be better adapted to drier environments or another may flower earlier in the growing season. Theoretically, a greater number of species, with different traits, will make more complete use of the available resources, increasing productivity beyond the maximum of any less diverse mixture of species. Complementarity of species in the use of nitrogen as a limiting resource and facilitation of one species by another as it occurs when a nitrogen fixer increases the availability of nitrogen to other species can cause productivity of diverse mixtures of species to be greater than the productivity of any of the single species.

Species diversity is often correlated with other factors, such as productivity, biomass, predation, or resource availability, that complicate the assessment of the effects of species diversity separate from other factors. Only a few studies have examined the effect of species diversity, independent of species composition, on nitrogen cycling. These initial results suggest that greater species diversity among the primary producers more completely uses the available nitrogen and increases plant uptake of nitrogen. In a Minnesota grassland, the NO_3^- concentration in the soil of the rooting zone (Figure 6) and below the rooting zone decreased with increasing diversity, indicating that less NO_3^- was lost via leaching and more nitrogen was retained within the ecosystem. In these same Minnesota grasslands, the nitrogen concentration in plants and the total nitrogen content of the plant biomass increased with the number of functional groups as well, and the

Figure 6 Effect of plant species diversity (number of species) in grassland plots on the concentration of nitrate in the soil (mg N/kg) containing most of the plant roots (0–20 cm). Reproduced from Tilman DG (1999) The ecological consequences of changes in biodiversity: A search for general principles. *Ecology* 80: 1455–1474.

composition and diversity of the functional groups had approximately equal influences on ecosystem processes. In California serpentine grasslands, temporal partitioning of resources and facilitation by nitrogen fixers allowed more complete use of the greater available nitrogen, but the identity of the functional groups was more important than the number of functional groups. Hypothetically, increased diversity and resource exploitation increase nitrogen retention, thereby creating a positive feedback loop of increased fertility and productivity. With more complete capture or immobilization of a limiting resource such as nitrogen, more diverse communities may be less susceptible to invasion.

Variability of NO_3^- in the rooting zone decreases as the number of plant species increases, but this is partly due to a simple statistical artifact – a ‘portfolio effect’ in which the aggregate variance of several species (like the diversified portfolio) is less than the variance of individual species. More diverse communities may show less variability in ecosystem function under the varying conditions typical in the natural world. Thus, species diversity may provide ‘insurance’ that regardless of the varying environmental conditions, ecosystem functions will be carried out by some species suited to the prevailing conditions.

In general, it appears that the number of species or functional groups may influence nitrogen dynamics, but these are probably less influential than the particular identities of the species or functional groups, especially within the context of the many other factors which strongly influence nitrogen dynamics, including climate, geology, hydrology, type and history of disturbance, etc. Species and functional group diversity may be most important at the very low diversity characteristic of intensively managed and exploited ecosystems typical of modern agriculture or very degraded ecosystems. It appears that the upper limit of the number of plant species for species diversity, independent of species composition, to have an impact on nitrogen cycling may be quite low (1–12) in most ecosystems. Of course, there may be some ecosystems in which nitrogen cycling cannot be maintained by a few species – perhaps extremely variable and heterogeneous ecosystems such as semiarid grasslands.

Considerations for the Future

Unfortunately, there is no obvious reason to expect human impact on nitrogen cycling or other human impacts on biodiversity to decrease. Rather, we can expect modification of the nitrogen cycle and declining biodiversity to continue, within the context of all the other modifications which we humans are making to our environment, including climate change, air and water pollution, and overexploitation of natural resources. Many indirect effects of alterations of the nitrogen cycle on biodiversity are possible. For example, human activities have increased the release of N_2O , a greenhouse gas which contributes to climate change. Climate change has potentially major effects on biodiversity. In addition, N_2O which reaches the stratosphere participates in the

destruction of the stratospheric ozone shield, allowing more ultraviolet light to penetrate to the earth’s surface, potentially decreasing biodiversity. The variety of important ecological interactions which involve nitrogen, the complexity of controls on nitrogen dynamics, and the huge scale of human alterations to the biogeochemistry of nitrogen imply that many more interactions and feedbacks between nitrogen and biodiversity remain to be discovered as the domination of the environment by humans intensifies. The interactions between nitrogen and biodiversity are multiple and complex, but it is clear that humans cause both the changes in the biogeochemistry of nitrogen that usually reduce biodiversity and the changes in biodiversity that alter the biogeochemistry of nitrogen.

This article is reproduced from the previous edition, volume 4, pp 509-522, © 2001, Elsevier Inc.

Pesticides have been in recorded use since 1000 B.C. Arsenic was in regular use as a garden insecticide in China by A.D. 900 and chemicals of one form or another have protected humans and their crops and livestock throughout the development of modern civilization. In comparison with this long time scale, we are still in the earliest phases of the use of synthetic organic pesticides, which were first used over large areas in the 1940s. There has, nonetheless, been sufficient time for several generations of pesticide chemistry to evolve, and pesticides have influenced all habitats and have affected the lives of all their inhabitants over this period.

Classification and Uses

Nowhere have the costs and benefits of modern technology been more difficult to reconcile than with pesticides. Benefits that include improved yield, crop quality, and food safety and reductions in vector-borne disease incidence have driven, and will continue to drive, their use. The earlier synthetic organic compounds were, however, flawed in their environmental behavior. They were persistent, they had a very broad spectrum of toxicological activity, and they displayed a tendency to be magnified in concentration through food chains, such that damage was inflicted to animal populations that lived beyond the treated area in habitats that were not intentionally contaminated. The discovery of some of these limiting impacts was only made possible through technical advances in, for example, analytical chemistry and conceptual advances where, for example, the ability to predict environmental behavior from chemical properties only developed after pesticides had been in use for decades. New pesticide discoveries are no longer accompanied by the marvel and optimism that characterized the first synthetic insecticides. Our ability to exploit these materials has, however, advanced considerably in recent years, and the chemicals themselves are increasingly specific in their impacts and appear to pose reduced risks. Scientists still question the value of reliance upon chemical pesticides, however, and modern pest control is characterized in general by a cautious approach to their management and use.

Set in a volume that will be consulted largely by biologists and ecologists with an interest in biodiversity, this article summarizes the chemicals that are in most widespread use and outlines the processes that contribute most to efficient delivery to the biological target. The nature and importance of toxicological and ecological effects are then reviewed, followed by a summary of procedures through which pesticides are regulated and managed. This article does not provide detailed reviews of biochemical mode of action, application, formulation, or environmental fate and behavior in any detail, and readers are recommended to pursue some of the literature

in the References section to gain insight into these important areas of pesticide science.

Uses of Pesticides

Pesticides may be classified by the types of pest they control (terms often bearing the suffix -cide; [Table 1](#)) or by the effects that they have upon the pest organism (terms that do not bear the suffix -cide; [Table 2](#)).

Table 1 Classification of pesticides by the type of pest controlled

Acaricide	Mites, ticks, and spiders
Adulticide	Adult insects
Algicide	Algae
Arboricide	Trees, brush, and scrub
Avicide	Birds
Bactericide	Bacteria
Fungicide	Fungi
Herbicide	Plants
Insecticide	Insect and sometimes related arthropod pests, including mites
Ixodicide	Ticks
Larvicide	Insect larvae
Miticide	Mites, ticks, and spiders
Molluscicide	Mollusks, such as slugs and snails
Nematicide	Nematodes
Ovicide	Invertebrate eggs
Piscicide	Fish
Predacide	Vertebrate Predators
Rodenticide	Rodents, including rats and mice
Silvicide	Trees, brush, and scrub
Termiticide	Ants and termites

Table 2 Classification of pesticides by effects on pests

Antifeedant	Inhibits feeding while insects remain on the treated plant
Antitranspirant	Reduces transpiration
Attractant	Lures pest to a specific location
Chemosterilant	Prevents reproduction
Defoliant	Removes foliage without immediately killing plant
Desiccant	Causes plant parts to dry
Disinfectant	Destroys or inactivates harmful organisms
Feeding stimulant	Causes vigorous feeding
Growth regulator	Stops, speeds up, or retards growth in insects or plants
Repellent	Drives away pests without killing them
Semiochemical	Pheromones and other substances emitted by plants or animals that alter animal behavior
Synergist	Substance that enhances the effects of a pesticide

Classification of Pesticides

Formulations

Pesticides are marketed in complex mixtures, or formulations, containing the pesticide chemical itself, the active ingredient (AI), and additives that enhance mixing and dilution in water or oil and release or deliver the toxic material once it has been applied. Common ingredients in a pesticide formulation include the AI, solvents, carriers, surface-active agents, and specialized additives. Solvent choice is determined by the solubility of the AI, potential toxicity to target plants (phyto-toxicity), toxicology, flammability, volatility, and cost. Some solvents are not miscible in water and cause emulsions to be formed (e.g., xylene), whereas others are selected because of their ability to dissolve the AI and their ability to dissolve in water (e.g., isopropyl alcohol). Carriers can include inert clays that disperse the active ingredient through a powder or granular formulation. Surface-active ingredients are used to assist in the process of emulsion formation (the dispersion of the pesticide liquid within the liquid diluent), but they also include wetting agents (materials that reduce surface tension and enhance wetting and coverage of surfaces), dispersing agents (materials that maintain the emulsion as microscopic droplets within the diluted formulation), and spreading agents (materials that enhance coverage of waxy plant foliage and insect cuticles).

The pesticide formulation may be in solid (i.e., powder or granule) form, or it may be a liquid or gas concentrate. Modern pesticides may achieve their intended effects at rates of less than 10 g per hectare ($10\,000\text{ m}^2=1\text{ ha}$), and the formulation blend enables these tiny quantities to be distributed evenly over the intended target surface.

A two-letter code denotes the formulation type on all pesticide labels, and this is a fundamentally important aspect of the selection of a pesticide for a particular use. There are four groups of formulation types:

- Group 1: Concentrates for dilution in water, including DC (dispersable concentrate), EC (emulsifiable concentrate), SC (suspension concentrate), and WP (wetable powder)
- Group 2: Concentrates for dilution with organic solvents, including OL (oil-miscible liquid) and OP (oil-dispersable powder)
- Group 3: Formulations to be applied undiluted, including GR (granules) and UL (ultra-low-volume (ULV) liquids)
- Group 4: Miscellaneous formulations, including RB (bait) and AE (aerosol dispenser)

Pesticide Types

Pesticides are characterized by their chemical diversity also. The summary below includes many of the most important groups of chemicals used in crop protection, but it is not exhaustive. Some pesticide properties are sufficiently uniform within the major classes of chemicals for this broad classification to be used in selection of chemicals for a particular use. Biochemical mode of action, for example, tends to be similar within major classes, and many crop protection programs use materials from several classes to avoid excessive selection pressure for resistance to pesticides. Other properties, are, however highly variable within pesticide classes as well as

between them. These include vapor pressure (volatility) and the various partitioning coefficients that determine the distribution and fate of the active ingredient in the environment. These properties determine the effectiveness of the pesticide against a specific target or in a specific climate type or habitat, and detailed knowledge of these properties is required for pesticide selection to be effective. Some aspects of properties will be dealt with later (*see Efficiency*).

Major Classes of Insecticides

Inorganic

These are mainly nonvolatile and water-soluble compounds that often have high mammalian toxicity and may also be cumulative poisons. Many are now discontinued or banned. They include materials such as boric acid, copper sulfate, mercurous chloride, and sodium arsenite.

Organic

Botanical These pesticides are derived from plant materials, some of which have low mammalian toxicity. Some have adverse effects on wildlife, including toxicity to fish. Examples include neem tree (*Azadiracta indica*) oil, which is used to protect stored products from insects; pyrethrum, from *Chrysanthemum cinerariaefolium*, a powerful but rapidly degraded insecticide that affects the peripheral nervous system, causing paralysis, known as “knockdown”; nicotine (from *Nicotiana tabacum*), an alkaloid insecticide that is also a neuromuscular poison in vertebrates; and rotenone, from the roots of *Derris* and *Lonchocarpus* spp., also used as a piscicide. Some of these materials are widely used in locally made or commercial formulations, and although they may be highly toxic, many are not persistent in the environment and degrade rapidly in sunlight or when exposed to microbial activity in soil or water. Each material has unique properties, and it is not possible to make generalizations about toxicology or environmental impact.

Organochlorines Organochlorines are synthetic pesticides, among the first to be developed. Early materials, including DDT, had dramatic early successes in vector-borne disease control, but most have adverse environmental impacts, resulting from persistence in the environment, accumulation through food chains, global redistribution of residues, and ecotoxicological impacts. Many organochlorines are now banned internationally. Examples include diphenyl aliphatics (DDT, dicofol, methoxychlor), benzene derivatives (HCH, pentachlorophenol), cyclodienes (chlordane, endosulfan, endrin), and polychloroterpenes (camphenchlor).

Organophosphates Organophosphates, or OPs, are esters of phosphoric acid. Many have high mammalian toxicity and may require frequent application because they are generally not persistent. Organophosphates are nerve poisons, acting through inhibition of cholinesterase. They fall into three groups: (1) Aliphatic organophosphates, which are the oldest group, some with low mammalian toxicity (e.g., malathion, which has been in use for 40 years) but others having high mammalian toxicity, but short persistence. Short persistence makes many OPs of use in short-season crops, where the plant or the consumer has a low tolerance for pests

(e.g., vegetable crops). Examples include, acephate, dichlorvos, dimethoate, malathion, and phorate. (2) Phenyl organophosphates, which are more stable and persistent but which include materials with high mammalian toxicity. Examples include fenitrothion, methyl parathion, and temephos. (3) Heterocyclic organophosphates, which may be more persistent and active in soil. Examples include azinphos-methyl, chlorpyrifos, phosmet, and pyrazophos.

Carbamates Similar to organophosphates, carbamates are esters of carbamic acid, with short residual life and a wide spectrum of activity. This group also includes some herbicides and fungicides. Some of the pesticides with highest mammalian toxicity are carbamates. Again, they divide into three groups: (1) Methyl carbamates with a phenyl ring structure, including carbaryl and methiocarb; (2) methyl and dimethyl carbamates with heterocyclic structures, including aldicarb and methomyl; and (3) methyl carbamates of oximes, having a chain structure, including bendiocarb.

Formamidines Formamidines are used as insecticides and acaricides, have the characteristic nitrogen structure $-N=CHN-$, and are effective against the eggs and larvae of Lepidoptera (butterflies and moths). They are useful alternatives to organophosphates, where resistance has developed. Examples include amitraz.

Dinitrophenols Dinitrophenols are broad-spectrum insecticides that have two nitro groups (NO_2) attached. Examples include binapicryl and dinocap.

Organotins Organotins are tin-based organic compounds that act as acaricides and fungicides, some with long residual activity. Examples include cyhexatin.

Pyrethroids Pyrethroids are synthetic compounds based upon pyrethrins, found in chrysanthemum flowers. They have similar toxicological properties but tend to be much more photostable and persistent. Natural pyrethrins occur in mixtures of six esters, and resistance is rare in the insects that they are used against. The synthetic pyrethroids are generally marketed as a single ester, and resistance may develop rapidly. Pyrethroids are generally of low mammalian toxicity but are highly toxic to fish and bees and beneficial predatory or parasitic invertebrates. Pest resurgence, or population outbreaks that result from the destruction of natural enemies, may occur in certain crops. Examples include allethrin, bioresmethrin, cyfluthrin, deltamethrin, and permethrin.

Fumigants Fumigants are insecticides that kill by vapor or gas action, have low molecular weight, and often contain halogen radicals. They can be highly toxic to vertebrates, particularly in enclosed spaces. Examples include chloropicrin, ethylene dibromide, and methyl bromide.

Petroleum Oils Petroleum oils, also known as mineral oils, have insecticidal properties. Light applications of refined paraffin oils can be made to trees in leaf. Lower viscosity, semirefined oils can be applied to dormant trees in winter to kill invertebrates and their eggs.

Antibiotics One antibiotic, abamectin, derived from *Streptomyces*, is an effective insecticide and antiparasitic agent also in veterinary use. There is evidence that when used in cattle, it can harm dung-feeding invertebrates. It has some systemic properties (i.e., it can penetrate leaves and be carried within the plant vascular system).

Semiochemicals Semiochemicals are behavior-modifying compounds, including pheromones, particularly the sex attractants of female moths. These may attract male moths for monitoring or be dispersed by spraying or formulation into controlled-release devices to establish false trails and disrupt mating of pest species. These compounds have very low environmental hazards, and the development of resistance is rare.

Insect Growth Regulators Insect growth regulators are compounds derived from, or inhibitory to, insect hormones and include methoprene, a juvenoid or juvenile hormone mimic, effective against mosquitoes, and diflubenzuron, which disrupts the synthesis of chitin and kills insects when they molt.

Microbials Included in this group are bacterial agents, particularly *Bacillus thuringiensis*, which is used against Lepidoptera, Diptera, and Coleoptera. A proteinaceous inclusion or endotoxin, which constitutes 40% of cell weight at sporulation, breaks down in insects with alkaline midguts to an active protoxin. This category also includes fungal diseases of insects, including *Beauveria bassiana*, *Metarhizium anisopliae*, and *Verticillium lecanii*, some of which can be formulated and sprayed like conventional insecticides. Some viral agents are also used on a large scale, including nuclear polyhedrosis viruses (NPV) of Lepidoptera. Microbial insecticides tend to have very limited effects on organisms that they do not directly parasitize, and vertebrate effects are almost unknown.

New Insecticides A series of new insecticides belonging to several previously unexploited classes of chemistry have been introduced in recent years. Some of these pose greatly reduced environmental risks, although this does not apply to all of the newer materials. These include imidacloprid (in the class chloronicotinyls), a highly systemic pesticide that is now used on a very wide scale. Research on these newer insecticides is limited at present, but there is optimism that ecological impacts and risks to wildlife will be greatly reduced as they become more widely used.

Major Classes of Fungicides

Inorganic

Inorganic fungicides are derived from sulfur or simple metal salts. They are generally stable, persistent, and insoluble in water. They include sulfur, which was originally applied as flowers of sulfur, in dust form, and which is still used, but in a more highly ground colloidal suspension. It has both direct contact and fumigant activity at temperatures above 20 °C, but above 32 °C the vapor may cause phytotoxicity (toxic harm to the target plant). Environmental damage and toxicological impacts to nontarget organisms are otherwise limited. Copper-based fungicides include Bordeaux mixture, an early fungicide that consists of a solution of copper sulfate and

hydrated lime. With 12% copper, this fungicide has low mammalian toxicity. A more stable form of copper (e.g., copper oxychloride) is used in modern formulations, enabling the slow release of copper into leaf surface water film and toxic buildup in fungal tissue. Other inorganic fungicides have included heavy-metal-containing materials that incorporate mercury, zinc, nickel, or chromium. These are normally highly toxic and persistent, and they have been banned internationally.

Organic

Organic fungicides have the reputation of being safer and less persistent than some of their inorganic counterparts, and they are often used at very low doses.

Dithiocarbamates Dithiocarbamates are derivatives of sulfur-containing dithiocarbamic acid, in combination with zinc salts, ferric salts, and manganese salts. These fungicides have greater efficacy, better stability, and less phytotoxicity than elemental sulfur. Their toxicity derives from the formation of the isothiocyanate radical ($-N=C=S-$) in breakdown. Compounds in this group include thiram, maneb, methamsodium, and zineb.

Organometallics This group of fungicides includes the following: (1) Mercury compounds, formerly popular for disinfective and protective action as well as volatility. They have high mammalian toxicity and are no longer available for any purpose. (2) Organocopper compounds, including copper acetate, which was first synthesized in 1899. These fungicides are not easily washed off leaves, being insoluble in water, and give persistent protection. They act by the nonspecific denaturing of proteins. Examples include cuproham. (3) Organotin, triphenyltin salts, including fentin, which can be both toxic and phytotoxic.

Substituted Aromatics These compounds include derivatives of benzene and phenol, with hydrogen atoms replaced by chlorine, nitrogen, and oxygen, and are suited for seed treatment and control of soil-borne fungi. Examples include chlorthalonil and pentachlorophenol (PCP).

Dicarboximides Also called sulfenamides, these compounds are considered to be among the safest pesticides in seed treatment and protectant sprays. Examples include iprodione and vinchlozin.

Phthalamides Phthalamides are used as nonsystemic, broad-spectrum, foliar fungicides on fruit, vegetables, and ornamentals. Examples include captan and captan, which is used widely in the tropics, but increasingly subject to restrictions.

Dinitrophenols These nonsystemic fungicides are used against powdery mildew and include the compounds binapacryl and dinocap.

Triazines This group consists mainly of herbicides, with anilazine as the only fungicide, used as a protectant treatment in vegetables.

Systemic Compounds

These fungicides are absorbed and translocated through plant tissues and provide longer term, protective control, with some curative and therapeutic effects for plants that are already infected. There are many groups, some of which are summarized below:

Oxathiins Oxathiins control basidiomycete fungi and include the compounds carboxin and methfuroxam.

Benzimidazoles and Thiophantes Benzimidazoles and thiophantes are broad-spectrum fungicides and are widely used in the tropics; intensive use has often led to resistance. Some of these compounds replaced organomercury fungicides as seed dressings. They include benomyl, carbendazim, and thiabendazole.

Pyrimidines Included in this class of compounds are bipirimate and ethirimol.

Acylalanines This class of compounds includes metalaxyl.

Ergosterol Biosynthesis Inhibitors (EBIs) Ergosterol biosynthesis inhibitors are a heterogeneous group of compounds with a common mode of action. They can have systemic, protective, and curative properties. They include (1) imidazoles (e.g., imazalil and prochloraz), (2) piperazine, pyridine, and pyrimidine compounds (e.g., pyrifenoxy and triforine), (3) morpholines (e.g., dodemorph and tridemorph), and (4) triazoles (e.g., flutriafol, myclobutanil, and propiconazole).

Organophosphates Organophosphates are a group consisting mainly of neurotoxic insecticides but also include fungicides such as pyrazophos.

Phenylamide and other Fungicides against Oomycetes This is another heterogeneous group, sharing the property of toxicity to oomycete fungi. High specificity and systemic activity help to confer resistance when used intensively. Included in this group are (1) phenylamides (e.g., benalaxyl and metalaxyl) and (2) the compounds cymoxanil and prothiocarb.

2-Aminopyrimidines This small group of systemic fungicides has activity against powdery mildew and includes bupirimate.

Quinones This group includes benodanil and futoril.

Other Organic Fungicides A number of important fungicides do not belong to the groups above, but comprise a random selection of compounds with unrelated chemical structures. They include chlorothalonil, dodine, guazatine, and thiocyclam. Most are nonsystemic, protective fungicides.

Major Classes of Herbicides

Herbicides kill or interrupt the growth of plants. Some are selective, but others kill all plants that come into contact with them and are used in industrial settings and in rights-of-way maintenance.

Inorganic Herbicides

This class includes mostly salts that have been in use for a considerable time. Sodium arsenite solutions and arsenic trioxide were popular in the 1960s but are now banned. This class also includes iron and copper sulfates, which are used for foliar application. Sulfuric acid has been widely used in horticulture and cereal crops as a selective herbicide. These materials are water soluble and readily leach from soil. Further examples include sodium salts of boric acid (borates) and sodium chlorate.

Organic Herbicides

Organic Arsenicals These materials are much less toxic to mammals than inorganic arsenic salts. They inhibit metabolism, competing with phosphate in essential reactions. These compounds include disodium methanearsenate (DSMA).

Phenoxyaliphatic Acids Herbicides in this group are a series of compounds in which the phenoxy nucleus is linked with acetic, propionic, and butyric acids. Solubility in water is high relative to that of many herbicides. They have selective, hormone-type effects on broad-leaved weeds, but grasses are tolerant. 2,4-D, 2,4,5-T, and MCPA were immensely popular and once regarded as safe. In the 1970s, dioxin contamination was suspected in 2,4,5-T and its registration was canceled.

Substituted Amides This is a large group of organic nitrogenous herbicides, including amides and anilides. Amides primarily act in soil against annual grass weeds, causing stunting. They have low mammalian toxicity and include chlorthiamid and propyzamide. Anilides, which have numerous subgroups, are used in postemergence grass and broad-leaved weed control as well as in preemergence compounds to control germinating weeds and grasses. All have low mammalian toxicity (e.g., alachlor and propanil).

Diphenyl Ethers These compounds possess two benzene rings, joined through oxygen or a more complex chain of molecules. They include preemergence and selective postemergence compounds of low mammalian toxicity. They are fairly insoluble in water, do not leach, and may be persistent for several months. Examples include diclofop methyl and oxyfluorfen.

Dinitroanilines Dinitroanilines are the most widely used group of herbicides in agriculture. They have a dinitroaniline nucleus in common and are effective against annual grasses and broad-leaved weeds when applied preemergence. Degradation occurs through volatilization and photodecomposition. Mammalian toxicity is low, and in soil persistence can be quite long. This class of compounds includes benfluralin and trifluralin.

Substituted Ureas Based on the simple nitrogen-containing molecule urea, the first example, monuron, was discovered in the 1950s as a total herbicide. More modern compounds are used as selective, preemergence herbicides that are strongly adsorbed to soil. They inhibit photosynthesis, causing

chlorosis. These compounds have low mammalian toxicity and their efficacy is influenced by temperature, rainfall, and soil type. Examples include chloroxuron, diuron, isoproturon, and linuron.

Carbamates In addition to many insecticides and fungicides, a number of herbicides have been developed from this chemical group. They include pre- and postemergence materials that inhibit germination and cell division. They have low mammalian toxicity and short persistence. Examples include asulam and phenmedipham.

Thiocarbamates The thiocarbamates are a group of carbamates containing sulfur, including selective pre- and postemergence compounds. The -allate compounds may persist for many months in soil. Metham sodium is a soil fumigant, converted in the soil to methyl isothiocyanate. Examples include diallate, metham sodium, and thiobencarb.

Heterocyclic Nitrogens These compounds have a ring structure where the carbon atoms are replaced by nitrogen or sulfur. They include triazines, triazinones, triazoles, pyridines, and uracils. *Triazines* are a very selective group of compounds; selectivity depends upon the plant's ability to metabolize the AI. They are soil applied and absorbed through roots, inhibiting photosynthesis once the plant has emerged. Mammalian toxicity is generally low, and intense application in some areas has led to groundwater contamination and restrictions upon use. Examples include atrazine and simazine. *Triazinones* have six-membered rings and include hexazinon. *Triazoles*, with a five-membered-ring structure, are active against broad-leaved weeds (e.g., amitrone). Some *pyridines* are effective against deep-rooted herbaceous weeds, and others are selective brush killers (e.g., picloram and trichlopyr). *Uracils*, another substituted, six-membered-ring family of chemicals with two nitrogen atoms and a double bond, are primarily for preemergence application and uptake by roots. They are effective at controlling annual grasses and broad-leaved weeds over an extended period by inhibition of photosynthesis. Uracils may be very persistent. Examples include bromacil and lenacil.

Bipyridiliums, also Termed Pyridines Containing two pyridyl rings, this group includes some extremely well known and widely used compounds (e.g., diquat and paraquat). They have contact action on the above-ground parts of plants and in the plant they are reduced to free radicals that destroy tissue under light. They are widely used as desiccants. These compounds are deactivated by sorption to the soil and slow to degrade, leading to increasing restrictions. Both AIs are hazardous, being the main cause of pesticide-related death in many countries. There is no known antidote.

Aliphatic Acids This group includes chlorinated derivatives of acetic acid, trichloroacetic acid (TCA) and dalapon. These compounds are used on non-cropland and in forestry, killing the plant by causing precipitation of proteins within cells.

Phenol Derivatives Herbicides in this group are highly toxic, selective, foliar herbicides and include dinitrophenols

and one chlorinated phenol, pentachlorophenol. Dinitrophenols, primarily contact herbicides, inhibit respiration and photosynthesis (e.g., dinoseb (DNBP), DNOC) and are now banned in the United States. Pentachlorophenol is now being banned in Europe and the United States.

Benzonitriles or Substituted Nitrites These compounds consist of a benzene ring with a cyanide ($C\equiv N$)- radical and are broad spectrum, acting on various processes of growth and tissue disruption (e.g., dichlobenil and ioxynil).

Miscellaneous Herbicides Herbicides with unrelated chemical structures include some widely used materials such as endothal sodium, an aquatic weed killer, glyphosate, a nonselective, residual, postemergence herbicide, and alloxym sodium, fluazifop-butyl, and other selective, post-emergence systemic herbicides, used against perennial and annual grasses.

Efficiency

Ideally, the receiving organism receives a toxic dose of pesticide and nontarget organisms escape injury, achieving high efficiency of use. Efficiency is, however, very rarely measured. When it has been, efficiency is far from ideal when expressed as the proportion of the applied dose taken up by the target organism or the amount needed to directly combat an infestation by treating it directly (Table 3).

What should our expectation for efficiency be? High efficiency cannot be expected in all circumstances. For example, many applications are made before serious infestations ensue, and pests are few in number or widely dispersed. It is generally agreed, however, that there is considerable scope for improvement in the efficiency of pesticide delivery, through attention to application, formulation, and the optimum delivery of the AI through attention to the physicochemical properties of the compound. The interaction between the pesticide and organism that leads to chemical exposure and uptake is termed bioavailability. The term *availability* describes the profile of chemical concentration over time, a function of

physicochemical properties, transfer, and sorption within the treated environment.

Delivery and Bioavailability

The toxic effects of a pesticide against any intended target or unintended nontarget organism are a function of intrinsic toxicity (the activity when it is directly applied to the organism) and the amount that reaches the organism under the conditions of application. The amount that the organism is exposed to depends upon placement (which is a function of application method), pattern of release (a function of the formulation), redistribution and transfer processes (a function of the physicochemical properties of the pesticide, environmental conditions, and the nature of the substrate), and the location and receiving characteristics of the organism. The latter is a function of the degree of contact or avoidance of the chemical, the activity of the organism in question, and, on a large scale, the spatial dynamics of the organism as it relates to the pattern of treatment and the persistence of the chemical.

Application, Formulation, and Delivery of the Toxic Dose

Through application and formulation, it is possible to manipulate the placement, size, and composition of the discrete units or drops of pesticide in which it is dispensed and the rate of release from those units or particles.

Soil Treatment

Some of the most difficult challenges relate to the problem of delivering sufficient pesticide to small targets distributed in a bulk medium in which mobility is restricted and the chemical subject to rapid degradation. It is therefore important to localize the pesticide to the vicinity of the target and plant part that needs protection. For example, granular formulations and seed treatments can both be used to increase efficiency of transfer of pesticide to organisms in the soil. Once applied, the chemical must move into the soil matrix and the rate of release determines the concentration in the soil. Diffusion and redistribution can be achieved by bulk flow of water moving down through the soil profile after rain or irrigation. Contact

Table 3 Utilization efficiency of pesticides

<i>Pesticide</i>	<i>Method of application</i>	<i>Target organism</i>	<i>Utilization efficiency (%)</i>	<i>Explanation</i>
Demeton-S-methyl	Foliar spray	Aphids on sugar beet	0.000008	Insects located in heart leaves, an effective refuge from direct spraying
Dieldrin	Seed treatment	Wheat bulb fly larvae	0.0015	Pests less likely to encounter seed as plant develops
Dimethoate	Foliar spray	Aphids on field beans	0.03	Relatively low efficiency of spray retention by plant
Lindane	Foliar spray	Capsids on cocoa	0.02	Pesticide losses due to drift when treating large trees
Lindane/dieldrin	Aerial spraying of swarms	Locusts	6.0	Pesticide applied by aircraft within swarm, maximizing chance of contact

between the water network in soil pores and the coated seed is very important.

Efficiency, or the toxicity of soil-applied AI per unit of material released, is determined by the way in which the chemical partitions between the solid, liquid, and air phases of the soil. The partition coefficients between these different phases can be used to accurately predict the rate of movement of pesticides within a given soil type.

Spray Application

Spray application is the commonest method of pesticide delivery. It is convenient, flexible, and simple, but it lacks selectivity and there is a risk of contaminating nontarget areas. Hydraulic sprayers give a range of pesticide drop sizes, at the smallest extreme of which there is a tendency to drift away from the target area. Controlled droplet application (CDA) sprayers are much rarer, but they control drop size and as a consequence may reduce drift and increase efficiency.

The main function of spray machinery is to transfer energy to the liquid pesticide formulation to atomize it into droplets by means of a nozzle. The drop size distribution is typical for the nozzle in question and it is characterized by the volume median diameter and the number median diameter of the drops.

- Volume median diameter (VMD): If a sample of spray is divided into two equal volumes, then half of the volume contains drops with a diameter less than the VMD, and the other half contains drops with a diameter greater than the VMD.
- Number median diameter (NMD): If the drops are divided in half by number, independent of volume, then the diameter of half of the drops is larger than the NMD, and the diameter of the other half is smaller.

The NMD : VMD ratio indicates the spread of drop sizes: the larger the ratio, the broader the spectrum. If the ratio approaches 1, the drops are all of a similar size and behave in a similar way.

Conventional spray application through hydraulic nozzles presents a major challenge for optimization of pesticide use efficiency, and their widespread use accounts for a great deal of pesticide drift and off-target exposure and contamination. **Table 4** provides details of the drop spectrum from a

conventional fan jet hydraulic spray nozzle. Drops of between 1 and 50 μm in diameter account for only 4.2% of the volume, but 90.8% of the total drops in the sample. In addition, 61.9% of the volume of the spray liquid is in drops of greater than 160- μm diameter. In 1 liter of spray liquid, this would yield nearly 90 million drops with a diameter of less than 50 μm , and therefore would be susceptible to drift.

Drop behavior has been the subject of detailed research. Drops are subjected to various forces as they leave the nozzle and before they impact on a surface.

- Gravitational forces: Small drops have a low terminal velocity. For example, a 5- μm -diameter drop falls at 0.075 cm/sec and often drifts from the target area, whereas a 500- μm -diameter drop falls to the ground at 213.9 cm/sec.
- Movement induced by air movement: Wind carries drops away from the target area. For example, in a wind of 1 m/sec, a 5- μm -diameter drop released from 1 m experiences 350 m of sideways transport, whereas a 500- μm drop moves 0.48 m. To deposit within 5 m of the target area, a drop must have a diameter of greater than 67 μm in a wind speed of 0.7 m/sec and it must have a diameter of greater than 168 μm in a wind traveling at 3 m/sec. The friction of the air rapidly decelerates drops from the velocity at which they left the nozzle. For example, a 5- μm drop is decelerated to its deposition velocity in 0.33 cm and a 200- μm drop is brought to the equivalent velocity in 630 cm.

Drift is worse where relative humidity is low. Drops become smaller as spray liquid evaporates and sedimentation takes longer. If 1 liter of liquid is atomized to 10- μm drops, then the cumulative surface area is 600 m^2 . If it is atomized to 100- μm drops, then the surface area falls to 60 m^2 . Evaporation is therefore exacerbated by the shrinkage of drops and the increase of relative surface area.

Large drops pose an equivalent problem: not deflected by air currents, they gain momentum and either miss the plant target and hit the soil or strike the plant, shatter, and fall to the ground. The cubed relationship between diameter and volume means that the volume of a 100- μm -diameter drop is 1 million times that of a 1- μm -diameter drop. The variation in pesticide dose between a 4- and 400- μm -diameter drop (common in a hydraulic nozzle drop spectrum) is 1 million fold. Many drops of a diameter greater than 300 μm fall to the ground, and a large proportion of the pesticide applied by a hydraulic nozzle

Table 4 Drop sizes from a hydraulic spray nozzle measured with a laser particle size analyzer

Drop range (μm)	Volume (%)	Cumulative volume (%)	Number (%)	Cumulative number (%)
563–262	26.17	61.94	0.07	0.80
262–160	35.77		0.75	
160–113	17.52		1.36	
113–84	8.78		1.82	
84–65	4.81		2.31	
65–50	2.73	4.22	2.86	90.81
50–30	2.66		8.45	
30–15	1.12		21.90	
<15	0.27		60.46

never comes into contact with the pest, disease, or weed it is intended to control.

Deposition on Obstacles

Objects are surrounded by a cushioning layer of air, and spray drops require considerable momentum to hit a target. Larger drops strike targets, and smaller drops move around them. The probability of striking depends upon the shape of the object; hairs, for example, pick up small drops. Flying insects such as mosquitoes are best hit by drops of 10–20 μm in diameter, resting flies require drops of 30–40 μm , diameters of 90–130 μm are needed where crop penetration is needed, and a diameter of > 250 μm is optimal for horizontal surfaces such as weeds.

Continuing reliance upon hydraulic spray technology limits the efficiency, effectiveness, and safety of the spray application process.

Ecotoxicology and Management

Pesticides pose challenges through being toxic to organisms other than the specific pests, diseases, or weeds they are

targeted against. Relative toxicity is expressed in a number of ways, but the most prevalent relates to oral and dermal exposure of mammals, which equates to both human and vertebrate wildlife toxicological risks for organisms that are directly exposed (Table 5).

Table 6 lists some representative active ingredients by toxicity and demonstrates that in all major pesticide types and range of classes, there is a considerable variety in intrinsic toxicities to mammals.

It is extremely difficult to translate these data, or toxicological data for any other species, into predictions of ecological risk. Very toxic materials may be relatively non-hazardous in the environment, because they are rapidly sorbed or dissipated, whereas less toxic materials may prove hazardous because they readily leach or runoff into water or because they are persistent.

Recent attempts have been made to bridge the gap that exists between basic toxicology and environmental chemistry and the potential ecological impact of pesticides in ecosystems. Van Straalen and van Rijn (1998) computed species sensitivity distributions for soil fauna (soil invertebrates that contribute to biogeochemical cycling), based upon laboratory

Table 5 Pesticide toxicity classes

Toxicity rating	<i>LD₅₀, single oral dose for rats (mg/kg)</i>	<i>LD₅₀, single dermal dose for rabbits (mg/kg)</i>	<i>Probable lethal oral dose for humans</i>
6, supertoxic	<5	<20	A taste, a grain
5, extremely toxic	5–50	20–200	A pinch, 1 teaspoon (5 ml)
4, very toxic	50–500	200–1000	1 teaspoon (5 ml) to 2 tablespoons
3, moderately toxic	500–5000	1000–2000	1 liquid ounce (30 ml) to 1 pint (470 ml)
2, slightly toxic	5000–15,000	2000–20,000	1 pint (470 ml) to 1 quart (950 ml)
1, practically nontoxic	> 15,000	> 20,000	> 1 quart (950 ml)

Table 6 Examples of pesticide toxicities to vertebrates from laboratory test data used in registration

Pesticide type and class	Pesticide technical name	Oral <i>LD₅₀</i> (rat, mg/kg)	Dermal <i>LD₅₀</i> (rat (a), rabbit (b))
Insecticides			
Organochlorine	Dieldrin	46	10 (a)
	Endosulfan	80	359 (b)
Organophosphate	Azinphos-methyl	16	222 (a)
	Chlorpyrifos	135	2000 (b)
	Dichlorvos	56	75 (a)
	Dimethoate	320	<130 (b)

^aKey: +, increase; =, no change; 0, variable result over the period of the study.

test data for toxic effects in soil, and calculated the concentration that would be below the no-effect concentration (NOEC: the highest dose not to cause a specific effect) for reproductive inhibition for 95% of the species that are theoretically present within the soil arthropod community. Using a simple model for pesticide fate, based upon exponential decay, they then calculated for a series of compounds the time that each product would take to reach this "95% protection level." This time, referred to as the "ecotoxicological recovery time," can be used as a basis for calculating the minimum time for ecological recovery to take place after pesticide application. There is considerable scope for further development of this technique, built upon readily collected toxicological data sets. Such data are, however, surprisingly difficult to find in the published literature, and they are not routinely collected for suites of compounds in such a way that they may be exploited within this new approach as a decision-making aid.

Table 7, adapted from van Straalen and van Rijn (1998), summarizes the differences in ranking of toxicity that result if pesticide toxicity to soil organisms and chemical persistence (half-life) in soil are integrated to predict the time when recovery could take place by organisms. A compound with high intrinsic toxicity, such as chlorpyrifos, has a lower ranking once its limited persistence is taken into account, whereas benomyl climbs higher up the rankings because of its persistence. Analytical procedures of this form are beginning to forge a link between the large amounts of laboratory-obtained

toxicological data that exist and the field, where functioning communities are exposed to the toxin, rather than individual species.

Farm-Scale Observations of Ecotoxicological Impact

A number of research projects investigating the ecology of farming systems were initiated throughout the 1980s and 1990s in Europe (Holland *et al.*, 1994). Pesticide impacts were investigated in all of these studies, and comparisons between conventional and reduced pesticide inputs were made in at least 13 sites, in Germany, The Netherlands, Switzerland, and the United Kingdom (**Table 8**). In all cases, beneficial non-target invertebrate densities were higher in areas where the total regime of pesticide input had been reduced. In the larger scale studies (e.g., the Boxworth study, UK), with 5.6- to 15.7-ha treatment area sizes, some beneficial species were rendered locally extinct for the full 5-year treatment phase of the project, and recovery was subsequently slow. The level of impact on individual species was shown to be a function of life history attributes that affected pesticide exposure and capacity of that organism to reinvade the treated area. Predatory capacity was inhibited in the highest pesticide regimes, and there was evidence that this contributed to higher pest densities in some years. Although similar data have been obtained for the invertebrate community of rice systems in the

tropics, data sets of this level of complexity are rare in the investigation of pesticide impacts in agroecosystems.

These investigations have revealed the subtler impact of second- and third-generation active ingredients that followed the organochlorines. They reinforce the need to measure ecological impacts on scales that reflect agricultural practice and pesticide use in the real world and that are tuned to the scale of dispersive movement of nontarget taxa. They have also triggered considerable interest in the mechanisms that underlie long-term depletions, even local extinction of certain species. Both scale of treatment and the mode and rate of dispersal of arthropods influence rates of population recovery following pesticide use, and the proximity of local refugia from which recovery can occur, and landscape features conducive to movement and colonization are important factors underlying extinction risk. Modeling may provide an appropriate tool for testing our understanding of invertebrate population processes at the agroecosystem level, but it does not substitute for the need to undertake a far greater number of manipulative experiments and monitoring programs that examine the spatial dynamics of nontarget organisms in sprayed farming systems.

Avian Impacts

The requirement for large-scale, field-based monitoring and experimentation is not restricted to terrestrial nontarget invertebrates. Avian toxicologists have long recognized that field-based studies provide unique and indispensable data for interpretation of pesticide effects on birds (Taub, 1997). Many of the most important effects of pesticides on birds, including eggshell thinning as a result of the bioconcentration of organochlorines through food chains, were originally detected and documented as a result of field-based observations. These effects also include endocrine disruption, food supply reduction or alteration, variation in sensitivity between species, and the synergistic effects of exposure to multiple compounds.

Aquatic Systems

Similar arguments may be applied to the investigation of pesticide effects on aquatic organisms. The recent decision in the United States to reduce the requirements for ecological data from multispecies test systems in the regulatory process has been criticized because it will reduce the probability of detecting biologically significant effects (Taub, 1997). These effects include indirect trophic-level impacts, compensatory shifts within a trophic level, responses that are associated with seasonal trends in populations, chemical transformations effected by organisms in the exposed system, and impacts that result from long persistence of either the parent product or toxic breakdown products.

In conclusion, there is now abundant evidence that pesticide impacts can evolve at the agroecosystem scale and that this requires the development of appropriately scaled monitoring or experimental systems. Toxicological data are of fundamental value in the initial evaluation of pesticides, but in their real-world applications, pesticides may also elicit ecological effects that reverberate through the system, long after

the chemical residues have become undetectable. Laboratory-based, single-species tests are limited in their predictive power for impacts in the field, and further development of the theory and methodology associated with ecological effects is required.

Tools for Pesticide Management

It is questionable whether we apply our knowledge about pesticides effectively at any stage following the regulatory permission to use a product in a specified way. Given the need to combine knowledge of chemical properties, fate and behavior, environmental attributes such as soil type, toxicology, and ecology, the challenge is considerable. In each of these disciplinary areas, however, there are considerable databases of knowledge and predictive models that can be used to interpret how a pesticide will behave in a given set of field conditions.

Attempts have been made to summarize clusters of pesticide properties in databases that may be used to compare the environmental and ecological risks posed by lists of candidate compounds for specific uses. These databases are not specifically tuned to local conditions; they do, however, combine many factors, including risks to wildlife, in the rankings that they generate, and enhance the capacity of the end user to make more informed decisions about particular uses. The most significant development in this field is the proposal to derive Environmental Impact Quotients (EIQ) for compounds from established databases of pesticide properties (Kovach *et al.*, 1992). The quotient combines farmworker effects (built from acute and chronic toxicity and plant surface half-life) with consumer effects (built from systemicity, soil and leaf surface persistence, and potential for groundwater contamination) and ecological effects (built from aquatic and terrestrial ecotoxicology). There is considerable scope for toxicologists to develop approaches such as this from first principles in order to make data available in a form that can be used to assist decisions in the field. Guided by EIQs, growers and their advisors could then plan pest control tactics that attempt to minimize nontarget impacts and track their progress with a rigorous and quantitative methodology that could also be explained to consumers.

Plant Phenology Changes and Climate Change

Tim Sparks, Technische Universität München, Germany; Poznań University of Life Sciences, Poland, and University of Cambridge, UK

Annette Menzel, Technische Universität München, Germany

© 2013 Elsevier Inc. All rights reserved.

Glossary

Maximum temperature The highest temperature recorded in a 24-h period (usually daytime), often then averaged across a calendar month.

Mean temperature The average of minimum and maximum temperatures.

Minimum temperature The lowest temperature recorded in a 24-h period (usually night-time), often then averaged across a calendar month.

Phenology The study of the timing of natural events, such as leafing or flowering.

Phenophase The phenological event that is being recorded, such as first leafing.

Synchrony The temporal matching of phenological events.

Phenological Data

The changing of the seasons in temperate zones has been the subject of human fascination for many centuries. Alongside prevailing weather, it forms a staple topic of conversation. It has been, and continues to be, economically important by dictating farming and forestry operations. This interest has resulted in various levels of organization of recording observations in the changing seasons.

Records of the timing of events, known as phenophases, typically concern the beginning, peak, or end of a particular botanical event. In the case of farming, these will also include operations such as the drilling and harvesting of a crop. It is simpler and less subjective to record the timing of a first or last event (such as leaf bud burst, first leaf, first flower, end of flowering, and trees bare) than it would be to record (by estimation or measurement) the date of the peak. In broad terms, the first and last events are more typical in networks involving many recorders while more specialized phenological recording, often using growth stages such as biologische bundesanstalt, bundessortenamt, and chemical industry (BBCH) codes (Meier, 1997), is more likely within research organizations.

Even for the simple phases, such as first flower, there is a clear need to have an accurate description of the event. Many will record first flower when the center of the flower is visible, but undoubtedly there are records made when the petals are still closed. In some species, flowering may be defined as when pollen is being released, for example, in grasses or in catkin species such as Hazel *Corylus avellana*. For plant species with complex leaves, such as Ash *Fraxinus excelsior* or Horse Chestnut *Aesculus hippocastanum*, the definition of first leaf needs careful attention. Autumn events associated with leaf color changes or leaf fall will also need clear definition. For perennial species, it is possible to record the same individual plant year after year, but this is obviously not possible for annual species. The more advanced networks of recorders, such as that operated by the Deutscher Wetterdienst (German Meteorological Service), provide both a written description and a photographic example.

The bulk of plant phenological data concerns events in spring, partly because these events are easier to record and partly because spring is psychologically more important: a time of rebirth and renewal. The Old Testament quotes “For, lo, the winter is past, the rain is over and gone; the flowers appear on the earth; the time of the singing of birds is come” Within spring events, leafing and flowering phases are clearly the most popular. The timing of spring must have been kept by Man since he could first keep records, but the oldest written records we are aware of come from the former Japanese capital of Kyoto where the dates of Cherry blossom festivals were recorded. In broad terms, national networks of recorders developed in three phases: from the 1870s under the auspices of learned societies, after the Second World War under the auspices of government hydrometeorological institutes, and in the 21st century in response to climate impacts monitoring (Figure 1). In addition to organized networks there have been many valuable records collected by

Figure 1 A diagrammatic representation of the intensity of phenological recording over the last three centuries.

individuals (e.g., Fitter and Fitter, 2002) and local groups (e.g., Abu-Asab *et al.*, 2001).

More recently, new technology has started to influence how we record the changing of the seasons. From 1981, it has been possible to assess the greenness of the Earth *via* satellite remote sensing. Data can be examined to see when spring arrives (when vegetation becomes photosynthetically active) over a large scale by assessing the “green wave” (Schwartz, 2003). This technology is unlikely to take over from traditional observations because there are still some problems associated with satellite images being obscured by cloud, the relatively low frequency of satellite recording (8 days), and the inability of a satellite to detect events such as flowering. More recently, options provided by remote image collection by digital cameras and webcams have started to be investigated. These overcome many of the frequency and cloud problems experienced by satellites, but still may fail to detect events such as flowering.

Phenological Response to Temperature and Other Environmental Drivers

Plant growth primarily requires light, water, mineral nutrients, and suitable temperatures. These apparently simple demands involve a large number of environmental factors and physiological processes, such as meteorological and edaphic as well as biotic factors, all of which may theoretically influence phenology. However, in temperate and boreal zones, the annual course of plant life is clearly split up: (1) a physiologically active growing season beginning with the recovery of photosynthesis and growth of evergreens (visible in phenology as “May shoots”) or bud burst of deciduous plants (“leaf unfolding”) and (2) a dormancy period during winter with cessation of growth and higher frost resistance. Prior to this, in autumn, the chlorophyll of deciduous leaves is decomposed (“leaf coloring”) and finally leaves are shed to reduce the evaporative surface area in winter and to avoid frost damage (“leaf fall”).

This synchronization of the morphological and physiological status of plants to the seasons is primarily triggered by temperature and day length. The photoperiod roughly restricts growth to suitable time periods, within which the timing of spring events, such as bud burst, leaf unfolding, and flowering, is mainly regulated by temperature: chilling temperatures break winter dormancy and subsequent warm temperatures induce bud burst.

Thus, as long as the chilling requirements are fulfilled, the phenological onset of spring correlates very well with air temperature of the preceding months. Many studies have shown strong, significant correlations between winter/spring temperatures and phenological spring phases, such as bud burst, leaf unfolding, or flowering in mid and higher latitudes (see Menzel, 2003; Root *et al.*, 2003; Sparks and Menzel, 2002; Walther *et al.*, 2002), which seems to be nearly linear over a broad temperature range (Figure 2, also Figures 3 and 4). Menzel *et al.* (2005) demonstrated that this response of spring events to temperature exists both for temperatures at the larger scale and for local climate station data. Even for time series

covering the last century, no renunciation of the linearity at the warmer temperature tail is apparent.

An extensive survey of several European countries comprising 254 mean national records revealed that most phases correlated significantly with mean monthly temperatures of the month of onset and the two preceding months (Menzel *et al.*, 2006a). For 19% of the phenophases the highest correlation was with the month of onset, 63% with the preceding month, and 18% with temperature 2 months earlier. For spring and summer, and most of the autumn fruit-ripening phases, the mean correlation coefficient was negative. Thus, higher temperatures are related to earlier onset dates; for example, in flowering and leaf unfolding the average correlation coefficient was -0.69 . Often the temperature response is quantified by means of linear regressions. The comprehensive European study further showed that spring and summer phases advanced by up to 4.6 days per $^{\circ}\text{C}$ warming, with an average advance of 2.5 days per $^{\circ}\text{C}$ and autumn leaf coloring was delayed by up to 2.4 days per $^{\circ}\text{C}$ (average 1.0 days per $^{\circ}\text{C}$).

In addition, circulation patterns, such as the North Atlantic Oscillation which controls winter and spring temperature in the western parts of Europe, has been shown to explain up to 50% of the variability in spring phenological phases in Central and Northern Europe (e.g., Menzel, 2003). Consequently, spring phenological phases can serve as proxy data for spring air temperatures.

Autumn phenology of deciduous plants, such as leaf coloring or leaf fall, is generally more complex and in consequence less understood. Various environmental factors may drive autumn phenology, even the relationship between simple meteorological factors and leaf coloring/leaf fall is still obscure. Numerous hypotheses about weather or climate conditions modifying the onset of leaf coloring in temperate regions comprise occurrence of minimum temperatures, dropping of daily mean temperatures (inducing autumn dormancy), warm autumn weather and sufficient water supply (lengthening the growing season), high autumn temperatures (accelerating leaf coloring), warm June (promoting early leaf coloring), high radiation in autumn (inducing early leaf coloring), dry periods in summer (promoting leaf coloring), and some sort of constant length of the growing season or constant temperature sums (see Estrella and Menzel, 2006). Only at the regional level can it be deduced that warm August and September delay leaf coloring, whereas warm May and June advance it.

Other possible triggering factors for spring phenology discussed are soil moisture and atmospheric CO_2 concentrations. In many areas of the mid and higher latitudes, soils are mostly water saturated at the end of winter and the start of spring, thus soil moisture is not a limiting factor and has not been shown to influence phenological onset dates. However, there is some experimental and historical evidence for the Mediterranean climate zone that geographical changes in rainfall produced significant, complex, and strongly species-specific, as well as spatially and temporally variable, phenological effects (Penuelas *et al.*, 2004). The effect of elevated atmospheric CO_2 concentration, although it increased from a preindustrial value of 280 to 380 ppm nowadays, cannot be deduced from observational data. Experimental evidence suggests that there are only limited effects. For example, in

Figure 2 Beginning of flowering of *Aesculus hippocastanum* at stations in Germany vs. monthly mean air temperatures in March/April (a) using mean temperature for Germany TYN CY 1.1 dataset (Documentation for the TYN CY 1.1 data-set, 2006) and (b) using temperature data from adjacent climate stations of the German Meteorological Service. Reproduced from Menzel A, Estrella N, and Testka A (2005) Temperature response rates from long-term phenological records. *Climate Research* 30: 21–28, with permission from Inter-Research.

100-year-old temperate forest trees at the Swiss Canopy Crane site near Basel, Switzerland with 4 years of 540 ppm CO₂ atmosphere, phenological variables, such as bud break, leaf fall, and leaf duration, were highly species-specific and were not affected by elevated CO₂ in any consistent way (Asshoff *et al.*, 2006).

Evidence for Phenological Change

The fourth assessment report of the Intergovernmental Panel on Climate Change (IPCC, 2007) concluded that temperature changes have already affected many physical and biological systems. Among the biological systems affected, phenology is one of the prominent bioindicators of climate change as their

timing is strongly related to weather and climate. Since 2001, more and numerous studies have also demonstrated an earlier onset of spring events for mid- and higher latitudes and a lengthening of the growing season. Reviews and meta-analyses of this documented literature reveal a consistent pattern of change across the Northern Hemisphere (Parmesan and Yohe, 2003; Root *et al.*, 2003; Sparks and Menzel, 2002; Walther *et al.*, 2002; IPCC, 2007). The average advance of spring events amounted to 2.3 days per decade (Parmesan and Yohe, 2003) derived from 677 multispecies studies from any location that reported neutral, negative, and positive results. The second meta-analysis by Root *et al.* (2003) reported a stronger advance of 5.1 days per decade, because of restricting the analysis to publications reporting significant changes of one or many species.

Figure 3 The relationship between Oak leafing (black symbols and line), Bluebell flowering (gray symbols and line), and January–March mean temperature.

Figure 4 The relationship between Garlic Mustard flowering (black symbols and line), Lady's Smock flowering (gray symbols and line), Orange Tip butterfly appearance (open symbols, dashed line), and January–March mean temperature.

However, published single-site or single-species studies are particularly open to suspicion of being biased toward predominantly reporting climate change-induced impacts. Therefore, the European COST725 study analyzed an enormous systematic phenological network dataset of more than 125,000 observational series of 542 plant and 19 animal species in 21 European countries (1971–2000) (Menzel *et al.*, 2006a). Across Europe, 78% of all leafing, flowering, and fruiting records advanced (30% significantly) and only 3% were significantly delayed, whereas the signal of leaf coloring/fall was ambiguous. This shows that the previously published results of phenological changes are not biased by reporting or publication predisposition; the average advance of spring/summer in Europe almost exactly matched the result by Parmesan and Yohe (2003) of 2.5 days per decade.

In addition to these apparent changes in spring, a lengthening of the growing season has been observed in the mid- and higher latitudes of the Northern Hemisphere. Here, the

different approaches based on phenological, satellite, and climatological studies reveal comparable results: a lengthening of the growing season of *ca.* 10–20 days in the last few decades, mostly owing to an earlier start (e.g., Menzel and Fabian, 1999; Walther *et al.*, 2002).

A coherent pattern of observed change does not mean equal changes across species and regions. Nearly all studies analyzing multispecies datasets found species-specific differences (see reviews by Sparks and Menzel, 2002; Walther *et al.*, 2002). In many cases, species resuming growth and activity earlier in spring exhibit the strongest advances in recent decades (Sparks and Menzel, 2002; Menzel *et al.*, 2006a; Menzel *et al.*, 2006b). In flowering, Fitter and Fitter (2002) deduced that annuals had advanced flowering more than congeneric perennials, and insect-pollinated species more than wind-pollinated ones. In a UK based meta-analysis, Thackeray *et al.* (2010) concluded that advances in terrestrial plant phenology were greater than those for terrestrial invertebrates or vertebrates. Furthermore, several studies have pointed out regional differences, for example, observed changes in spring are more pronounced in Western than in Eastern Europe. Quite interestingly, an earlier start of the growing season is linked to a higher spatial variability, which may imply further consequences of these observed changes (Menzel *et al.*, 2006b).

Consequences of Change

Plant species occupy a niche, environmentally and temporally. They persist only if conditions are suitable for their growth and reproduction. At some point in their life cycle they compete for resources with other plant species (competitors), they may be dependent on plant or animal species (allies), and they will invariably be subject to damage by animals (grazers). In earlier sections, it was very clear that plant phenology has changed as a consequence of a changing climate. Change has also been observed in the phenology of many invertebrate and vertebrate species.

If the phenology of the plants, their competitors, their allies, and their grazers all change in synchrony then it is obvious that the *status quo* will be maintained. However, this is clearly not the case (e.g., Fitter and Fitter, 2002) and we have to consider what the consequences may be of differential change in phenology. Some species are highly adaptable to changing environments (including climate) but as a consequence of this success they are typically a pest or a weed problem, and these species may do very well in a changing climate. Those that show an inability to respond may suffer from local extinction if competition or grazing increases, or if they lose synchrony with their allies. If they have low powers of dispersal, that is, the inability to move to an analog environment, then extinctions could be more widespread.

The consequences of phenological desynchrony are, as yet, less studied. However, this is a key area of research needed to inform conservationists where effort should be focused if biological diversity is to be maintained. Fitter and Fitter (2002) found clear differences in the changes in flowering phenology in British plants. Annual species had changed more than perennials, insect-pollinated species more than wind-pollinated species, and species close to the center of their

geographical range more than those further away. They also detected examples where opportunities for hybridization between related species would both increase and decrease. If a plant species is specialized to the insect species that pollinates it then phenological synchrony is likely to be more critical than if it can be pollinated by a range of insect species. Synchrony issues with grazers may be more critical for the herbivorous insects than for the plant species themselves, although marked changes in herbivory may affect plant growth. Specialized herbivorous insects may depend on one or a few plant species, but, in addition, at the correct developmental stage and hence nutritional value. A commonly used example uses Oak trees *Quercus* spp. and Winter Moth *Operophtera brumata* (e.g., Buse *et al.*, 1998) where phenological development of both leaves and caterpillars is very responsive to temperatures, but caterpillars must feed on the young leaves before tannin levels become too high.

In the recent past, there was considerable concern that Bluebells *Hyacinthoides non-scripta*, a characteristic flower of ancient woodlands in the UK, would suffer from earlier canopy closure, that is, exclusion of sunlight. However, both this herb and the dominant canopy species appear to be temperature responsive. In Figure 3 are shown the response of Bluebell flowering and Oak *Quercus robur* leafing to January–March temperature. Data are taken from a single observer (A. Phillips) in the English West Midlands between 1976 and 2004. Both have highly significant ($p < 0.001$) regression lines; Bluebell -9.7 ± 2.0 days per $^{\circ}\text{C}$ and Oak -5.6 ± 1.3 days per $^{\circ}\text{C}$. Although the regression slopes are not significantly different ($p = 0.103$), there is some suggestion that, at higher temperatures, Bluebells may gain extra days of direct sunshine before the canopy leaves. Such a suggestion needs further examination from more data; ideally, from both more years and more locations. Broad statements like this have to be tempered by the known greater phenological variability in warmer, and hence earlier, springs (Menzel *et al.*, 2006b).

Data from the same location can also be used to examine the relationship of flowering of Garlic Mustard *Alliaria petiolata*, Lady's Smock *Cardamine pratensis*, and the emergence of the Orange Tip butterfly *Anthocharis cardamines* whose caterpillars feed on the seed heads of these plants (Figure 4). The regression coefficient on January–March mean temperature of Garlic Mustard flowering is -7.1 ± 0.9 days per $^{\circ}\text{C}$, that of Lady's Smock -3.4 ± 1.2 days per $^{\circ}\text{C}$, and the Orange Tip -5.4 ± 1.6 days per $^{\circ}\text{C}$. All coefficients are very significant ($p \leq 0.01$) and those of the two flowers are significantly different from one another ($p = 0.015$). This graph suggests that the butterfly may lose synchrony with Lady's Smock at higher temperatures, but maintain it with Garlic Mustard and that the latter may become a more important larval foodplant as the climate warms.

Unresolved Questions

It is clear from the previous section that the consequences of differentially changed phenology are not yet known. The conservation community has serious concerns that a breaking down in synchrony could be very serious for some species (Root *et al.*, 2003). The most susceptible species are likely to

be those that exist at low population levels, in isolated communities, have specific ecological niches, have low powers of dispersal, and have low responsiveness to temperature. In other words, adaptable species are likely to benefit, and specialists suffer, from rising temperatures. These are, however, broad statements and should be treated with caution. Plant species do not exist in isolation from one another but in balance with their competitors, allies, and grazers. A change in status in any of these will affect the balance and there are too many permutations to make prediction a simple task.

Another issue to further muddy the waters is the introduction of new species. These could be either species expanding their geographical range in response to environmental change or could be alien species (such as garden escapes), which may have “jumped the garden fence” as the local climate becomes more suitable for their reproduction and persistence. There are numerous examples of exotic species, for example, Rhododendron *Rhododendron ponticum* and Japanese Knotweed *Fallopia japonica*, becoming serious environmental problems. Prediction of the effect of new species into existing communities is also at a very early stage.

Analysis, like that summarized in Figures 3 and 4, will typically fit a linear relationship between phenology and temperature. This straight line can only be an approximation to the real relationship and only be valid over a relatively narrow range of temperatures. There is no doubt that, in seasonal climates, there is a limit to how far a plant species can advance its leafing, flowering, or fruiting, or delay its leaf fall. Future warming is predicted to push our environments into new, nonanalog, situations outside of our experience. What will happen to these species at these new temperatures? It may be possible that we can gauge their reaction by looking at their situation in warmer parts of their distribution, although this is likely to be within a different plant community. Can species adapt, for example, through genetic selection? If so, how much can they change and over what timescale? Species with high-generation turnover and high reproduction rates are likely to be more adaptable. Many of these species are called weeds!

We have hardly touched in this article on autumn phenology because the changes so far experienced are more mixed and the drivers of change much more complex; probably involving temperature, sunshine, soil moisture, diurnal temperature range, and windiness. This is another area requiring more attention.

Finally, most research has involved a comparison with temperature, and typically with either mean temperatures or accumulated temperature sums. What has been lacking is an examination of the effects of extreme events (drought, frost, etc.) and the consequences of increased frequency in these extremes.

Demonstrating the responsiveness of plant species and differential response is relatively easy. Prediction of the consequences of change in face of the huge number of permutations of climatic change and plant-community structure is much more complex.

Soil Biota, Soil Systems, and Processes

David C Coleman, University of Georgia, GA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Domains The major divisions of the biota on earth, namely: Bacteria, Archaea, and the Eucarya.

Ecosystem engineers The concept whereby members of the macrofauna (e.g., termites and earthworms) are actually moving parts of the soil volume for their own uses (e.g., making macropores which permit flow of large amounts of water rapidly through the soil).

Immobilization The process wherein nutrients are taken up or immobilized in litter and other organic detritus until later (usually weeks to months) in the decomposition process.

Larger mesofauna and macrofauna Live in pores in portions of soil profiles.

Microfauna Animals that have high turnover rates, and live in water films in soils. Small mesofauna, such as nematodes, are also water-film dwellers.

Mineralization The availability of inorganic nutrients in the decomposition of organic detritus, occurring after the immobilization phase.

Organizing centers Soils are the centers of history and activity in terrestrial ecosystems.

Soils as Components of Ecosystems

Soil-Forming Factors

Soils are an intriguing, relatively thin (often <1 m depth) zone of physical–chemical and biological weathering of the earth's land surface. Soils are formed by an array of factors, namely climate, organisms, parent material, the extent of slope, and aspect (relief) operating over time (Figure 1). These factors affect major ecosystem processes, such as primary production, decomposition, and nutrient cycling, which lead to the development of ecosystem properties unique to that soil type, as a result of its previous history. For example, a deep loess soil in Iowa, with a very fertile and deep surface or "A" horizon, containing considerable amounts of organic matter, will be very different from an "A" horizon developed in the Nebraska sandhills, with much greater porosity and lower water retention due to the nature of the sandy surface material. As noted in the soil-forming factors diagram (Figure 1), the array of biota – namely microbiota, vegetation, and consumers (herbivores, carnivores, detritivores) – is influenced by the soil processes and in turn has an impact on the soil system.

Polyphasic Nature of Soils, Influence on the Biota

Soils are perhaps the ultimate in interface media, located at the intersection of four principal entities: the atmosphere, biosphere, lithosphere, and pedosphere (Figure 2). Soils provide a wide range and variety of microhabitats, thus accommodating a very diverse biota. The microbes (bacteria and fungi) are found in numerous microsites, well-aerated or not; bacteria may thus respire either aerobically or anaerobically. There is an enormous amount of surface area (hundreds of m² per gram of soil) on the soil particles, which range in size classes from clays (0.1–2 µm in diameter) to silts (2–50 µm diameter) and sands (0.05–2 mm diameter). Numerous microbes and micro and mesofauna (protozoa and nematodes) exist in water films on these particles and in or on the surfaces of microaggregates formed from the primary particles. In turn,

the more mobile fauna, from collembola and mites (larger mesofauna) to the macrofauna (earthworms, millipedes, ants, termites, and fossorial or earth-dwelling vertebrates), move through the macro and micropores in the soil. The macrofauna play a role in moving parts of the soil profile around and form many sorts of burrows and pores; they are often termed as "ecological engineers."

Soils as Organizing Centers in Ecosystems

Soils may be viewed as the organizing centers for terrestrial ecosystems. Major functions such as ecosystem production, respiration, and nutrient recycling are controlled by the rates at which nutrients are released by decomposition in the soil and litter horizons and transported to the photosynthetic layers of the ecosystem. This is particularly true for less heavily managed, near-natural ecosystems, many of which occur on soils having relatively poor nutrient status. In these systems, mycorrhizas are often obligate partners in the obtaining of adequate nutrients for the growing plants. Mycorrhizas (literally "fungus roots") are efficient at extracting nutrients from both mineral and organic sources, enabling plants to thrive in habitats that are considered to be poor in nutrients. We need to be aware of these and other mutualistic associations between microorganisms and roots, such as rhizobia and actinorhizas, various root-associated symbiotic bacteria that facilitate the nitrogen fixation process on which the entire ecosystem often depends. These associations have arisen in soils over an evolutionary time and are key to an understanding of the ecosystem function.

Major Soil Processes

Decomposition: Immobilization and Mineralization

A very large proportion (greater than 90%) of the terrestrial net primary production is returned to the soil as dead organic

Figure 1 Soil-forming factors and processes, and the interaction over time. Reproduced from Coleman DC, Reid CPP, and Cole CV (1983) Biological strategies of nutrient cycling in soil systems. *Advances in Ecological Research* 13: 1–55; and Coleman DC, Crossley Jr. DA, and Hendrix PF (2004) *Fundamentals of Soil Ecology*. San Diego: Academic Press.

litter. This litter, consisting of leaves, roots, and wood from trees and organic residues from agricultural fields, is decomposed on or in the soil, and the nutrients contained within it are recycled for further use. The decomposition process drives complex food webs in the soil, with numerous interactions between the initial agents of decomposition, the bacteria and fungi, and the fauna which in turn feed on them.

Decomposition is the catabolism of organic compounds in plant litter and other organic detritus. Decomposition is principally the result of microbial activities; few soil animals have cellulases in their guts, which allow them to hydrolyze the celluloses in plant residues. The decomposition of organic residues involves the activities of a variety of soil biota, including both microbes and fauna, which interact conjointly in the process. For example, the initial breaking up of plant litter usually is conducted by the chewing and macerating action of

both large and small animals. This initial breaking into smaller pieces, or “comminution,” is a process that benefits the fauna, which derive nutritional benefit from the litter or microbes initially colonizing the plant material. The increased surface area and further inoculation of the smaller pieces enhances the microbial access to, and breakdown of, these tissues.

Nitrogen Cycle: Major Processes

Nitrogen enters the ecosystem via nitrogen fixation, in which the dinitrogen molecule (N_2) is separated into two nitrogen atoms, with considerable expenditure of energy and the assistance of the nitrogenase enzyme, to break the triple covalent bond. The atoms are ammonified and then used in the production of amino acids and proteins in the plants. Another

avenue for nitrogen entry into the soils is by lightning fixation, in which the extensive high-voltage energy in the lightning charge ruptures the dinitrogen molecule, hydrogens are attached, and then the ammonium is brought in by rainfall. As shown in **Figure 3**, nitrogen is lost from the system via harvest and erosion of organic forms of N, it can be ammonified in decomposition, and then undergoes nitrification to nitrate

Figure 2 The pedosphere showing interactions of abiotic and biotic entities in the soil matrix. Reproduced from FitzPatrick EA (1984) *Micromorphology of Soils*. London: Chapman and Hall; and Coleman DC, Crossley Jr. DA, and Hendrix PF (2004) *Fundamentals of Soil Ecology*. San Diego: Academic Press.

(NO_3^-), after which it can be taken up by biota, either through plant roots or into microbial tissues. If there is adequate energy and low amounts of oxygen present, there can be denitrification, in which the nitrogen is lost as either nitrogen gas (N_2) or nitrous oxide (N_2O). For further details, consult textbooks on ecology or ecosystem studies.

The nitrogen cycle is of critical importance to biodiversity considerations, because key points in the cycle are dependent on the relatively species-poor assemblages of microbes, including the nitrogen fixation and nitrification steps. There are only a few species of nitrogen-fixing rhizobia, in the genera *Rhizobium* and *Bradyrhizobium*. The other principal nitrogen-fixing symbiont, the bacterium *Frankia* (Actinomycetaceae) forming the actinorrhiza (literally actinomycete-root), contains only a few species in the genus. However, approximately 194 plant species in eight families and four different subclasses of flowering plants have been identified as hosts. These plants share the general tendency to grow in marginal soils and play an important role as pioneer species in early successional habitats.

In the nitrification steps, noted in the previous paragraph there are only a few genera and species of nitrifiers. Most of them are autotrophic and quite sensitive to changes in soil pH. This means that these organisms may be unusually prone to getting diminished or eliminated in regions where there is considerable acid rain.

Biodiversity in Soils

Evolutionary History

Soils as we know them, with well-differentiated profiles, probably developed concurrently with the origin of a land

Figure 3 Inputs and outputs of N, which make up the intersystem transfers in an ecosystem. Numbers indicate groups of organisms active at a given stage of the N cycle. (1) *Rhizobia*, *Frankia*, (2) ammonifiers, (3) nitrifying bacteria, and (4) denitrifying bacteria. Denitrifying bacteria must compete with the biotic uptake of NO_3^- by other microbes and plants; thus the rate of nitrification sets an upper limit on denitrification losses. Stream water losses represent the excess of available N over that taken up by biotic processes. Modified from Waring RH and Schlesinger WH (1985) *Forest Ecosystems*. Orlando, FL: Academic Press.

flora in the early Devonian era, about 450 million years ago. The microorganisms that inhabit the soils, particularly the prokaryotic microbes such as the cyanobacteria, originated perhaps 3 billion years ago.

Diversity of Biota

Biodiversity is an inclusive concept, which encompasses a wide range of functional attributes in ecosystems in addition to being concerned with the numbers of species present in the system. This differentiates it from the concept of species diversity, which is concerned with the identity and distribution of species in a given habitat or region.

Soil biodiversity is best considered by focusing on the groups of soil organisms that play key roles in ecosystem functioning. Spheres of influence (SOI) (Coleman, 2008) of soil biota are recognized, such as the root biota, the shredders of organic matter, and the soil bioturbators. These organisms influence or control ecosystem processes, and exert further influence via their interactions with key soil biota (e.g., plants). What is the extent of redundancy within the functional groups of these SOI? Some soil organisms, such as the fungus and litter consuming microarthropods, are very speciose. For example, there are up to 170 species in one order of mites, Oribatida (members of the Arachnida, eight-legged arthropods), in the forest floor of one watershed in western North Carolina. In the soil biota, some of the species-poor functional groups, such as specialized bacteria, that is, nitrifiers and nitrogen fixers (Figure 3) are considered, at present, to be at most risk. Others include fungi forming mycorrhiza, a symbiotic association that benefits both plant and fungus, with the plant supplying high-quality carbon to the fungus, and the fungal hyphae exploring a greater volume of the soil, obtaining scarce mineral nutrients, particularly phosphorus. Other species-poor functional groups include macrofaunal shredders of organic matter (e.g., millipedes) and bioturbators of soils, which include various types of earthworms and termites.

Three Great “Domains” of Organisms on Earth

All of life exists in three great “kingdoms,” or domains. These domains are (1) the Bacteria (eubacteria), which are the bacteria as generally considered; (2) Archaea (archaeobacteria), which include the methanogens (methane-producers), most extreme halophiles (ones living in hypersaline environments), and hyperthermophiles (ones living in volcanic hot springs, and in mid-sea ocean hot-water vents); and (3) Eucarya (eukaryotes) (Figure 4). The first two domains are prokaryotes, which are unicellular organisms, lacking a unit membrane-bound nucleus and other organelles, usually having their DNA in a single circular molecule. Eukaryotes, in comparison, consist of all of the organisms that have a unit membrane-bound nucleus and other organelles, such as mitochondria (Woese *et al.*, 1990). Eukaryotic organisms are often multicellular. This scheme is based on an increasing body of evidence from ribosomal RNA (rRNA) phylogenies, that the archaeobacteria are worthy of the same taxonomic status as eukaryotes and bacteria. As shown in Figure 4, the universal

rRNA tree develops from a postulated “cenancestor,” leading to the relative positions of the three great domains (Pace, 2009).

Number of Species of Prokaryotes

Recent estimates of the number of prokaryotic species range from 100,000 to 10 million. Interestingly, the number of species of bacteria so far described in soil amount only to about 4000. This discrepancy is largely due to the fact that only a small proportion, usually less than 1%, of the bacteria present in soil or any other medium are amenable to culturing and subsequent microscopic observation. Most taxonomic descriptions of prokaryotes are made using some variants of 16S rRNA probing, using molecular techniques.

It should be noted that, on the basis of the accepted criterion for separating taxa in microbial studies, which is greater than 70% DNA homology, a mouse and a human would be considered as being in the same species. This leads to complications, as we shall see, in discussing the total amount of genetic diversity of all organisms, including the yet largely unknown diversity of Archaea and Eubacteria. The latter now are estimated to have an array of 100 phyla, which are genetically as diverse as the phyla in Animalia, Plantae, and Fungi in older classification systems.

Biomass, Diversity, and Numbers of Bacterial Species on Earth

The Bacterial biomass and numbers are often vastly underestimated. We are currently delineating the overall genetic makeup of isolates taken from soils, which are determined by the use of molecular probes. The total numbers of bacteria on earth in all habitats are truly staggering: $4\text{--}6 \times 10^{30}$ cells, or 350–550 petagrams of carbon (Whitman *et al.*, 1998). One petagram is 10^{15} g, or 1 billion metric tons. The number of bacteria that are calculated to exist in soils is approximately 2.6×10^{29} cells, or about 5% of the total on earth. A majority of bacteria exist in oceanic and terrestrial subsurfaces, especially in the deep mantle regions, extending several kilometers below the earth's surface.

Knowledge of the diversity of archaea and bacteria is still limited, but with the use of new massive parallel sequencing devices (Roche 454 and other pyrosequencing techniques), we are beginning to approach an understanding of the very large biodiversity of these organisms. More than one full decade into the “genomic era,” it is necessary to consider a bacterial species as described by its pan-genome, which is comprised of a “core genome” containing genes common in all strains and a “dispensable genome,” containing genes present in two or more strains and genes unique to only one or two unique strains. In essence, the pan-genome of the bacterial domain is of nearly infinite size. For example, in eight genomes representative of the serogroup diversity among group B *Streptococcus* (GBS) strains, the pan-genome contains 2713 genes, of which 1806 belong to the core genome and 907 belong to the dispensable genome. The GBS pan-genome is predicted to grow by an average of 33 new genes every time a new strain is sequenced. However, this pattern does not hold for all bacterial species.

Metagenomics encompasses the full array of microorganisms present in an ecosystem at any point of time (Dinsdale *et al.*, 2008). Metatranscriptomics refers to the number of microbes in a given community or ecosystem that are respiring or

Figure 4 Schematic drawing of a universal rRNA Tree of Life showing the relative positions of groups in the domains Bacteria, Archaea, and Eucarya. The location of the root (the cenancestor) corresponds to that proposed by reciprocally rooted gene phylogenies. (Branch lengths have no meaning in this tree.)

synthesizing at a given time. At any given moment, an estimated 10^{30} bacterial and archaeal genes are mediating essential ecological processes throughout the world (Moran, 2009).

Viruses as Quasiorganisms

Viruses are quasiorganisms, not included in the three domains. Viruses are RNA or DNA molecules contained within the protein envelopes. Viral particles are metabolically inert, carrying out neither biosynthetic nor respiratory functions. They multiply only within the host cells, by inducing a living host cell to produce the necessary viral components. Once assembled, the replicated viruses escape from the cells. Viruses infect all sorts of animals, plants, and microbes. Viruses parasitizing bacterial cells are commonly called bacteriophages, or simply phages. Although little is known about the ecology of viruses, they can persist in soils for many years and decades. Some research on viruses in deserts showed that they were inactivated in soils at acid pH levels between 4.5 and 6. There is little information on the overall species diversity of viruses in soils. Current estimates are 5000 species known and perhaps 130,000 in existence.

Considerable new knowledge of virus ecology is being gained in aquatic realms: limnology and oceanography. Very little is known about viruses and their ecology in soils, despite their known effects on beneficial bacteria and soil-borne plant pathogens and horizontal gene transfer (transduction). Estimates from 5% to 25% of the carbon fixed by primary producers enter into the microbial loop via virus-induced lysis at

Figure 5 Pelagic food chain model and virus-mediated carbon flow (Reproduced from Kimura M, Jia Z-J, Nakayama N, and Asakawa S (2008) Review—Ecology of viruses in soils: Past, present and future perspectives. *Soil Science & Plant Nutrition* 54: 1–32, with permission from Wiley.). The dotted lines show virus-mediated pathways. All values are based on the flux of carbon fixed by primary producers (100%).

various trophic levels in the aquatic environments (Figure 5). Despite the concerns about the amount of viral adsorption to soil particles, particularly clays, the greater physical and chemical diversity of soils makes it possible that viruses have an even larger potential to play roles that are similar to those in the aquatic environments.

Figure 6 Map of the Marseillevirus chromosome. Rings correspond to genome coordinates in kilobases, proteins and protein-coding genes. The pie chart inside the ring represents taxonomic breakdown of Marseillevirus genes by probable origins inferred by phylogenetic analysis or sequence conservation. NCLDV, nucleocytoplasmic large DNA virus of eukaryotes. Reproduced from Kimura M, Jia Z-J, Nakayama N, and Asakawa S (2008) Review – Ecology of viruses in soils: Past, present and future perspectives. *Soil Science & Plant Nutrition* 54: 1–32.

Because there are an estimated 10^{31} phages on the planet and they can move between environments, the potential reservoir of genes that can be transferred both locally and globally by phage is enormous. There is little restriction to the types of genes carried by the viral community, suggesting that they influence a wide range of processes, including biogeochemical cycling, short-term adaptation, and long-term evolution of microbes.

Recent molecular studies of mechanisms to fend off phages and other forms of invasive DNA, including clustered regularly interspaced short palindromic repeats are increasing the ways in which we can quantify phage and prokaryotic interactions. Although the current usage of phages in soil biological control studies has focused primarily on the plant-pathogenic bacteria, the existence of consortia in which insects, bacteria, and viruses interact in a complex five-way mutualistic symbiosis is a proof that interactive complexities exist and are worth exploring. The time scale of viral evolution and the diversity of viral linkages that emerged during that extended time period would explain why the viral-specific genes probably outnumber the cellular ones in metagenomic studies, which forms a very large reservoir of molecular diversity.

As an example of virus–microbial–eucarya interactions, consider the giant Marseillevirus, a previously uncharacterized giant virus of amoebae. The genome repertoire of the virus is composed of nucleocytoplasmic large DNA viruses (NCLDV), core genes and genes apparently obtained from eukaryotic hosts (Boyer *et al.*, 2009, Figure 6). There is a distinct possibility that amoebae are “melting pots” of microbial evolution where diverse forms emerge, including giant viruses with complex genetic repertoires of various origins.

Numbers and Biodiversity of Eukaryotes

Fungal Diversity

Fungi are multicellular eukaryotes that are found in many habitats worldwide. They have long, ramifying strands (hyphae), which can grow into and explore many microhabitats, and are used for obtaining water and nutrients. The hyphae secrete a considerable array of enzymes, such as cellulases, and even lignases in some specialized forms, decomposing substrates *in situ*, imbibing the decomposed subunits and translocating them back through the hyphal network. Fungi are abundant, particularly in undisturbed forest floors in which literally thousands of kilometers of hyphal filaments will occur per gram of leaf litter.

Table 1 Comparison of the numbers of known and estimated total species globally of selected groups or organisms

Group	Known species	Estimated total species	Percentage known
Vascular plants	220,000	270,000	81
Bryophytes	17,000	25,000	68
Algae	40,000	60,000	67
Fungi	69,000	1,500,000	5
Bacteria	3000	30,000	10
Viruses	5000	130,000	4

Source: Reproduced from Hawksworth DL (1991) The fungal dimension of biodiversity: magnitude, significance and conservation. *Mycological Research* 95: 641–655.

Fungi are still little-described, with possibly less than 5% of them known to science (69,000 described; perhaps 1,500,000) in existence (Table 1). This is largely because of the fact that so many fungi are associated with tropical plants and animals, and these in turn have not been described.

As noted at the beginning of this section the roles of mycorrhizas in soil systems are being increasingly viewed as central to much of terrestrial ecosystem function. The total number of mycorrhizal species may be just a few thousand, but they are essential to the growth and reproduction of numerous families of plants (van der Heijden *et al.*, 1998). Recent experimental studies have noted that species richness, namely with large versus small numbers of species of Arbuscular mycorrhiza, has a positive impact on plant primary production in macrocosms of North American old fields (fields undergoing succession and not intensively managed) (Harrison, 1997).

Microfauna

The unicellular eukaryotes, or Protoctista, include a wide range of organisms, which are more often called protists, or protozoans. These include the flagellates, naked amoebae, testacea, and ciliates (Figure 7). These organisms range in size from a few cubic micrometers in volume to larger ciliates, which may be up to 500 μm in length and 20–30 μm in width. Protozoa are quite numerous, reaching densities of 100,000–200,000 per gram of soil. Bacteria, their principal prey, often exist in numbers up to 1 billion per gram of soil. All of these organisms are true water-film dwellers and become dormant or inactive during episodes of drying in the soil. They can exist in inactive or resting stages for literally decades at a time in very xeric environments.

About 40,000 extant protozoan species have been described, but many more undoubtedly are awaiting scientific discovery. In an extensive survey of soils from Africa, Australia, and Antarctica, in some cases nearly half of the total species described were new to science. This was particularly true in Africa, where of the 507 species identified, 240 of them, or 47%, were previously undescribed. Even in a more extensively investigated region, Australia, 43% of the total of 361 species were new to science. In Antarctica, 95 species were described, with only 14% or 15%, being unknown.

Because many habitats have not yet been investigated, and the isolation procedures are still imperfect, 70–80% of all soil ciliates may yet be unknown. This high proportion may hold true for the other protozoan groups as well.

Mesofauna

Nematodes Nematodes feed on a wide range of foods. A general trophic grouping is bacterial feeders, fungal feeders,

plant feeders, and predators and omnivores. Anterior (stomal or mouth) structures can be used to differentiate general feeding or trophic groups. The feeding categories are a good introduction, but feeding habits of many genera are complex or poorly known. For example, some genera in immature phases will feed on bacteria and then become predators on other fauna once they have matured. Because of the wide range of feeding types and the fact that nematodes seem to reflect ages of the systems in which they occur (e.g., annual vs. perennial crops, or old fields and pastures and more mature forests), they have been used as indicators of the overall ecosystem condition.

As nematodes use a diverse range of food resources it is logical that their feeding, activity, and population dynamics will interact with other components of the ecosystem. For perhaps a century nematodes were almost exclusively regarded as pathogens having adverse effects on plant and animal production. Realization of their wider contributions to ecosystem processes developed in the 1970s, as did shifts toward managing rather than controlling populations of economically important parasites of plants and livestock and the use of nematodes as biocontrol agents for insects.

This is a growing area of research in soil ecology, and one in which the intersection of community analysis and ecosystem function could prove very fruitful. Current species of nematodes described total around 5000, and more than 20,000 may exist. For additional information on the activities of these diverse creatures, see Yeates (2010).

Collembola Collembolans, or “springtails,” are the primitive Apterygote (wingless) insects. They are called “springtails” because many of them have a spring-like lever, or furcula, which enables them to move many body lengths away from predators by using it in a springing fashion. Collembolans are ubiquitous members of the soil fauna, often reaching abundances of 100,000 or more per square meter. They occur throughout the soil profile, where their major diet is decaying vegetation and associated microbes (usually fungi). However, like many members of the soil fauna, collembolans defy placement in exact trophic groups. Many collembolan species will eat nematodes when those are abundant. Some feed on live plants or their roots. One family (Onychiuridae) may feed in the rhizosphere and ingest mycorrhizae or even plant-pathogenic fungi.

Eight families of Collembolans occur in soils. Many Collembolans are opportunistic species, capable of rapid population growth under suitable conditions. Eggs are laid in groups. Collembolans become sexually mature with the fifth

Figure 7 Morphology of four types of soil Protozoa: (a) flagellate (Bodo), (b) naked amoeba (Naegleria), (c) testacean (Hyalosphenia), and (d) ciliate (Oxytricha). Reproduced from Coleman DC, Crossley Jr. DA, and Hendrix PF (2004) *Fundamentals of Soil Ecology*. San Diego: Academic Press.

or sixth instar, but they continue to molt throughout their life. Although many species are bisexual, some of the common species are parthenogenic, consisting of females only. Collembolan “blooms” are a phenomenon of late winter or early spring, when some species may appear in large numbers on the surface of snow banks, on the surface ice of pond water, or on lichen-covered granite outcrops. There are some 6500 described species and possibly more than 10,000 in existence.

Mites (Acari) The soil mites, Acari, are chelicerate arthropods related to the spiders. They are often the most abundant microarthropods in many types of soils. A 100 g sample may contain as many as 500 mites representing nearly 100 genera. This diverse array includes participants in three or more trophic levels, with varied strategies for feeding, reproduction, and dispersal.

Four suborders of mites occur frequently in soils: the Oribatei, Prostigmata, Mesostigmata, and Astigmata. Occasionally, mites from other habitats are extracted from soil samples. These include, for example, plant mites (also called spider mites), predaceous mites normally found on green vegetation, and parasites of vertebrates or invertebrates. The most numerous ones are the true soil mites. The oribatid mites (Oribatei) are the characteristic mites of the soil and are usually fungivorous or detritivorous. Oribatid mites are very speciose, numbering 20,000 known species, with perhaps 60,000 yet to be described. A widespread assumption in the soil ecology literature has been that the oribatids feed on fungi of decomposing leaf and root litter, hence may have narrow niche overlaps in food items they consume. Recent studies in Europe have demonstrated a somewhat wider range of food items in oribatid diets that have been measured by the

stable isotope ratios ($^{15}\text{N}/^{14}\text{N}$). A total of four feeding guilds among 36 species or taxa were differentiated. In temperate deciduous and tropical forests, the Oribatids are very speciose. One notable example of high temperate zone oribatid diversity is that up to 170 species occur in just a few hundred square meters of the forest floor of a mesic, mixed deciduous forest watershed in western North Carolina. This species richness, or α -diversity (the diversity within a given site), exceeds that of some tropical forest oribatids. In a field study, species richness of oribatids declined with decreased litter species richness in experimental (1 m^2) enclosures from five down to one species of deciduous tree litter. The decline in oribatid species richness was attributed to the lower physical and chemical diversity of the available microhabitats from polyspecific to oligospecific litters, including leaf petioles, which specialized feeders such as phthiracarid ("box") mites would occupy preferentially.

Impacts of oribatid mites farther up the food chain, in ways not often considered by soil ecologists, have been demonstrated recently. In tropical America and probably in the tropics more generally, oribatids as a group contain as many as 80 alkaloids and represent a major dietary source of alkaloids in poison frogs. A conservative assumption is that they accumulate alkaloids from their food sources. To what extent do fungi or other organisms contribute alkaloids to the oribatids' diet?

Mesostigmatid mites are nearly all predators on other small fauna, although a few species are fungivores and may become numerous at times. Astigmatid mites are associated with rich, decomposing nitrogen sources and are rare except in agricultural soils. The Prostigmata contains a broad diversity of mites with several feeding habits. Very little is known of the niches or ecological requirements of most soil mite species, but some interesting information is emerging. For further details on the life-history characteristics of these interesting animals, see Coleman *et al.* (2004). About 20,000 species have been described and possibly more than 80,000 exist.

Macrofauna

Termites Termites (Isoptera) are one of the major ecosystem "engineers" particularly in tropical regions. Termites are social insects with a well-developed caste system. By their ability to digest wood, they have become economic pests of major importance in some regions of the world. Termites are arranged in five different families. The termites in a more primitive family, the Kalotermitidae, possess a gut flora of protozoans, which enables them to digest cellulose. Their normal food is wood that has come into contact with soil. Many species of termites construct runways of soil, or along root channels, and some are builders of large, spectacular mounds. Members of the phylogenetically advanced family Termitidae possess a formidable array of microbial symbionts (bacteria and fungi, but not protozoa), which enable them to process and digest the humified organic matter in tropical soils and to grow and thrive on such a diet.

Although termites are mainly tropical in distribution, they occur in temperate zones and deserts as well. Termites are often considered the tropical analogs of earthworms since they reach large abundances in the tropics and process large amounts of litter. Termites parallel earthworms in ingestive and soil turnover functions. The principal difference is that the

earthworms egest much of what they ingest in an altered form (that enriches microbial action), whereas termites can transfer large amounts of soil or organic material into building nests and mounds (carbon sinks). More than 2000 species of termites have been described, and probably up to 10,000 exist.

Earthworms The earthworm fauna of North America is surprisingly poorly known, given the importance of these animals to soil processes and soil structure. Much of the evidence for earthworm effects on soil processes comes from agroecosystems and involves a small group of European lumbricids (family Lumbricidae in the order Oligochaeta). In North America, south of the southern limit of the Wisconsinan glaciation, several native genera exist. However, exotic (often peregrine European lumbricids) earthworm species have been introduced into much of this area following human population changes and colonizations. Impacts of the exotic earthworms on native species are not well understood, although there is evidence that when native habitat is destroyed and native earthworm species extirpated, exotic earthworms colonize the newly empty habitat. As more extensive studies are carried out, it is becoming clear that earthworms are present in a wide variety of tropical as well as temperate ecosystems.

Earthworms play important roles in the fragmentation, breakdown, and incorporation of soil organic matter (SOM). This affects the distribution of SOM and also its chemical and physical characteristics. Changes in any of these soil parameters may have significant effects on other soil biota, by changing their resource base (e.g., distribution and quality of SOM, microbes, or small soil fauna) or by changing the physical structure of the soil. Recent evidence indicates that earthworm activities impact the communities of other soil biota through their effects on the chemical and physical characteristics of SOM, causing changes in the oribatid species richness and microarthropod abundances. It is probable that earthworm-induced changes in the microbial and microarthropod communities will also have impacts both higher and lower in the soil food web. Some 3650 species of earthworms have been described and possibly as many as 8000 exist.

Levels of Disturbance; Effects on Biodiversity

The impact of invasive species on plants and soil organisms is a subset of a more general phenomenon: the effects of various levels of disturbance on soil biodiversity. Several recent studies have shown little support for optimization of local soil animal diversity at intermediate levels of disturbance. In fact, a wide range of disturbances of soil by tillage could strongly elevate or reduce macrofaunal group diversity, but the diversity of microfauna was little affected. Apparently the magnitude of these effects depends on soil type, climate, and tillage operation. The overall consensus seems to be that in conversion from natural vegetation to agriculture, the diversity of a wide range of microbial communities and faunal groups, ranging from nematodes to earthworms and termites, is significantly reduced in the disturbed agroecosystems. Rigorous experimental testing of the disturbance–diversity relationship is still needed to ascertain its importance as a regulator of below-ground diversity. We must keep in mind the spatio-temporal

aspects of soil communities. Thus enhanced habitat complexity and diversity of available food resources will support localized “hot spots” of more diverse faunal communities. A more general aspect of disturbance studies is that related to land use and global change phenomena (Wall, 2004).

Conclusions

It is apparent that a large proportion of the biota associated with soils is as yet undescribed, with the most extreme cases being the bacteria and fungi. However, of even the somewhat more extensively studied groups, such as the oribatid mites, more than half remain unknown to science. Therefore, it is premature to give even a rough estimate of the total numbers of species that occur in many of these taxa; as such large percentages of the total number of organisms are still unknown.

When considering the diverse array of many kingdoms in all three domains of the biota, there are ample causative factors for the impressively large biodiversity observed in soils. These factors encompass many physically distinct microhabitats, organismal phenologies, numerous legacy effects, including stabilizing effects of SOM, and facilitation effects from many mutualistic interactions. In addition to the highly heterogeneous environment, a high degree of omnivory prevails in resource-use among the decomposer organisms, tending to reduce competition, and hence plays a major role in explaining the high degree of functional complementarity in decomposer communities. This is another way of considering soils as organizing centers in the terrestrial ecosystems (see Soils as Organizing Centers in Ecosystems).

It is incumbent on the rising generation of ecologists and biologists to develop more innovative ways to describe, catalog, and understand the myriad patterns and processes in the biosphere, which are due in large part to the actions of the biota. It is hoped that some of the observations in this article, plus the insights offered by the references listed will encourage this effort.

Stress, Environmental

John Cairns Jr., Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Acute An exposure to an environmental stress that is brief in relation to the temporal scale of the biological system exposed.

Biosphere All the plants and animals on Earth, together with the habitat they need for long-term survival.

Biotic impoverishment The decline of a species to the point of having little or no ecological significance.

Chronic An exposure to an environmental stress that is comparable in duration to the temporal scale of the biological system exposed.

Ecosystem services The structures and functions of natural biological systems which directly or indirectly support human life.

Environmental stress An action, agent, or condition that impairs the structure or function of a biological system.

Function The performance of a biological system as a rate.

Structure The number, kinds, and arrangement of component parts at one point in time.

Tipping point When a complex system goes into disequilibrium and is replaced by a new system in evolutionary time.

Uncertainty Imperfect knowledge concerning the current or future state of a system under consideration; a component of risk resulting from imperfect knowledge of the degree of hazard or of its spatial and temporal pattern of expression.

What is Environmental Stress?

Three components are involved in the relationship that defines environmental stress. First, there is the environmental stress itself as defined previously. However, the environmental stress can only be defined in reference to its interaction with some biological system. Therefore, there must be a receptor – a biological system that is exposed to the environmental stress. Finally, there must be an adverse response – a particular structure or function of the receptor that is changed by exposure to the environmental stress to the detriment of that system. If the survival of that biological system (or another) is not threatened by the change, then there is no environmental stress.

Types of Environmental Stress

Natural versus Anthropogenic

Environmental stress can be either natural or anthropogenic (i.e., resulting from human actions) in origin. Many environmental stresses, such as most hurricanes, droughts, floods, and fires are a periodic feature of life on Earth. In contrast, environmental stresses such as the production and release of new chemical compounds and large-scale land-use changes result directly from human actions. Ironically, the suppression of natural environmental stresses such as fires and floods can also be a source of stress to biological systems resulting from human actions. Some species have adapted to periodic disturbance and cannot continue without them. For example, some seeds will germinate only after exposure to the high temperatures of a fire. However, such adaptations take time to evolve. Other stresses, such as the meteor that probably wiped out 70% of earth's species 65 million years ago, occur too quickly and intensely to result in adaptation.

Natural and anthropogenic stresses often have common components. For example, both hurricanes and wood harvesting result in downed trees. However, as a result of recent major increases in human population, technological capabilities, and standard of living globally, the amount of anthropogenic environmental stress has increased greatly. Anthropogenic environmental stress existed even 50,000 years ago, when fires set to aid hunters are thought to have altered the landscape in central Australia (Flannery, 1999). Since that time, human population increased slowly to 1 billion people in 1804 and then rapidly to 6 billion people in 1999, and the population is expected to increase by another 1 billion people every 12–15 years. The cumulative environmental stresses resulting from these exponential increases in human population are exacerbated by technologies that expand the character and scope of changes humans can make to their environments. Both the agricultural revolution (about 10,000 years ago) and the industrial revolution (about 200 years ago) expanded the types of anthropogenic stresses on the environment. In addition, increased affluence for people throughout the world increases the environmental stress on natural systems by increasing the per capita human use of natural systems. Humankind's collective ecological footprint (i.e., the amount of earth's surface required to produce the resources used and to assimilate the wastes produced) is rapidly increasing (Rees, 1996) at the same time that productive land is decreasing through erosion, salinization, and unsustainable land-use changes. The ecological footprint for an average person can range from 0.4 ha required to provide for the lifestyle of one person in India, where the level of affluence is quite modest, to 5.1 ha for a person in the US. If the lifestyle of every person living in 1996 was elevated to that of a typical North American, an additional two earths would be needed to provide the surface area required (Rees, 1996).

Characterization of Environmental Stress

Environmental stresses of both natural and anthropogenic origin can be characterized on the basis of their spatial distribution, temporal distribution, intensity, and novelty (Kelly and Harwell, 1989). Spatial distribution of a stress describes its geographic extent and pattern. One basic concern is the size of the area affected by the stress, i.e., is the stress local, regional, or global in extent? Some kinds of environmental stress have an intrinsic spatial scale: A poorly dispersed chemical spill may be quite local in its effects, whereas air pollution can affect entire regions. Some stresses will be consistently spread over an area, whereas others will occur irregularly in patches. Cumulative environmental stresses, in which many individual small patches can join together to have larger impacts at a larger scale, have been documented. In one example at the local level, the cumulative loss of small wetland areas within a watershed had demonstrable adverse effects on water quality (Johnston *et al.*, 1988). The magnitude of the biological responses to a stress will often be modified by the spatial distribution of environmental stress, for example, whether key features in the environment such as riverbanks or fencerows are affected or whether similar habitat patches nearby are left unaffected. The field of landscape ecology deals with these factors.

The temporal distribution of a stress describes its frequency and duration. Some stresses, such as chemical spills, are one-time occurrences. Others, such as the winter season or wildfires, can be expected to reoccur either at predictable or at unpredictable intervals. Some stresses rapidly ameliorate; others remain for long periods of time. The terms “acute” and “chronic” are used to describe the duration of a stress. Acute refers to stresses of short duration, whereas chronic refers to stresses that last longer in relationship to the duration of the biological system they affect. In some cases, the timing of the stress in relationship to other biological events may modify the magnitude of the biological response. For example, the spawning season for amphibians in northern North America in spring corresponds to the greatest thinning of the ozone layer and ultraviolet (UV) light penetrations. The developing eggs of some of these species have been shown to be affected adversely by UV light (Blaustein and Wake, 1995). This temporal factor may be contributing to observed declines in the numbers and kinds of some amphibian species present in those areas.

The intensity of an environmental stress describes its relative ability to evoke a response from the receptor. With increasing intensity, the impact may progress from a few, slightly affected, particularly sensitive components of the biological system to most components being grossly affected. Small changes in the histology or physiological state of individual species can be expected to occur at lower stress intensity and chronologically before changes in survival at a similar temporal and spatial scale. Similarly, at the community level, changes in species composition can be expected to occur at lower stress intensity and chronologically before changes in the community functions. The intensity of hurricanes is routinely ranked from category 1 to category 5. In the case of chemical pollution, the intensity of the environmental stress can be described by the concentration of the chemical in the

environment. Thus, copper is a natural, background constituent of water in a river or stream. Intake of copper is essential for both animal and plant life. However, concentrations higher than $10 \mu\text{g l}^{-1}$ in river water can be expected to eliminate a few sensitive species and change the age class distributions in others by changing reproductive success. Higher concentrations can be expected to affect more components in more obvious ways. For example, in Shayler Run, Ohio, $120 \mu\text{g l}^{-1}$ of copper caused fish kills at some times of the year, avoidance of the stream reach by other fish, declines in macroinvertebrate community species richness, and other gross responses (Geckler *et al.*, 1976).

The novelty of an environmental stress will determine whether or not biological systems will have mechanisms in place to deal with it. Environmental stresses that resemble naturally occurring stresses in their mode of action will be dealt with by the system in the same ways. Novel stresses may be more devastating because no mechanisms have evolved to cope with them. For example, when human harvests of wood products mimic relatively frequent natural events such as treefall or windthrow in their spatial extent, mechanisms are in place in the biological system to recover from this event. When human-created gaps are larger and more intense than the historical disturbances, these same mechanisms may not help. Similarly, some natural systems can break down, render biologically unavailable, or disperse low levels of some chemical materials that are naturally occurring or that resemble naturally occurring substances without detectable disruption. The ability of a natural system to receive materials at some concentration, including anthropogenic wastes, without being degraded is its assimilative capacity. However, overloading a system with too much waste destroys both the structure and function of the ecosystem and its future assimilative capacity.

Receptors and Responses

An action, agent, or condition can be a stress to one biological system whereas simultaneously not affecting many others. Because environmental stress is defined by the observation of an impaired biological system, the probability of identifying an environmental stress is related to how thorough the search for impairment has been. Although there are an almost unlimited number of receptors and responses that could be affected by any particular environmental stress, it is generally impractical to monitor more than a small sample. Also, experience has shown that it is easy to overlook a response that may be important. For example, DDT caused eggshell thinning in some birds, although routine toxicity tests failed to identify this response.

The most useful responses to examine for studies that aim to influence decisions about environmental management tend to be those that are clearly related to stated environmental goals. These tend to be responses that are both biologically and socially relevant and that can be measured reliably. Sometimes, the responses that society cares most about cannot be measured directly. Other, presumably related, responses can be measured. In addition, responses that occur earlier in a chain of events, and which lead to an ecologically relevant

Table 1 Examples of receptors and responses used in studies of environmental stress

Level of biological organization	Structural responses	Function responses
Individual	Condition	Growth
	Fat stores	Fecundity
	Histopathology	Physiological function
Population	Occurrence	Yield
	Abundance	Gross morbidity
	Age structure	
Community	Species richness	Production
	Trophic structure	Respiration
	Proportion of exotics	Extinction rate
Ecosystem	Nutrient pool size	Materials cycling
	Biomass	Materials export
Landscape	Habitat proportions	Regional production
	Patch size	Materials export
	Perimeter-to-area ratio	Resistance to stress

event, may be useful as early warnings of conditions that have the potential to cause unacceptable damages. [Table 1](#) summarizes some responses that have been used to evaluate environmental stress and guide environmental management.

As the goals in environmental protection have changed over time, so have the responses that are monitored. Most early tests of environmental stress were designed to protect one species – humans. This objective spurred tests that monitored the physiology of species used as human surrogates. Gradually this protection was extended, first to domesticated animals and plants and then to commercially valuable wild species. These additional tests monitored the survival of populations of important species. Currently, goals extend beyond the protection of individual species and include the protection of biodiversity and ecosystem services (i.e., those structures and functions of natural biological systems that directly or indirectly support human life). Assessments should reflect these new goals because millions of species in the environment must be protected. Each species cannot be examined individually. In practice, a few species must serve as surrogates for many others, and a few systems serve as surrogates for many others.

Environmental responses may be characterized by type and scale. Responses are either structural (e.g., describing the number and kinds of components, such as the macro-invertebrate community structure) or functional (e.g., describing performance or flux, such as biological oxygen demand or primary production). Also, unique responses may occur at many distinct spatial and temporal scales and levels of biological organization (e.g., cells, tissues, organs, organisms, populations, communities, ecosystems, landscapes, biomes, and the world). Some attributes at higher levels of biological organization are not present at lower levels; for example, energy flow and nutrient spiraling are properties of ecosystems but not of organisms. Other attributes are present in some form at many levels; for example, one can measure the diversity of phenotypes at the population level and the diversity of species at the community level. Environmental goals can be stated on many of these levels, but tests of environmental

stress are largely limited to those levels that are more accessible to human observation.

An awareness of scale provides two contrasting approaches to study environmental stress. Top-down methods start with observed damage to a biological system of interest and investigations move down through hierarchical levels. Component structures and functions are examined in order to diagnose the causative agent and plan remedial actions. At the outset, the damage has already been done, so the relevance of the changes is known. However, the causative agent and the chain of events leading to unacceptable damage are not known. Bottom-up methods start with an environmental stress, and the effects of that stress on biological systems are determined through designed experiments. Because experiments on small and quick biological systems at lower scales are generally less expensive, these experiments are most common. In bottom-up assessments, the causative agent is known at the outset, but the importance of ultimate changes at any ecologically relevant higher scale is not known.

Microcosms and mesocosms are attempts to increase the spatial and temporal scales and level of complexity in biological systems that can be used in designed experiments of environmental stress. Microcosms and mesocosms simulate important attributes of natural systems in laboratory or outdoor conditions. As the names indicate, the main difference is in size. Microcosms are sometimes small enough to hold in one's hand; mesocosms may cover one acre. Neither is an exact reproduction of any real ecosystem, but they do enable studies of environmental stress in ways that avoid damaging natural systems. On rare occasions, environmental stress may be studied in designed experiments using entire ecosystems. For example, one whole system manipulation was carried out in the Hubbard Brook drainage basin in New York State ([Bormann and Likens, 1979](#)). Such efforts are of great value in calibrating models.

A General Environmental Stress Syndrome

A threshold is defined in Webster's *Third International Dictionary* as "the point at which a physiological or psychological effect begins to be produced." Moving upwards in biological systems, this effect can be generalized to the point at which a response begins to be produced. [Woodwell \(1974\)](#) asked the question

Is it reasonable to assume that thresholds for effects of disturbance exist in natural ecosystems or are all disturbances effective, cumulative, and detrimental to the normal functioning of natural ecosystems?

Thresholds may be artifacts of testing procedures, reflecting the power of particular test designs rather than a feature of the system being studied. However, perhaps the more important question is "Can humans detect those environmental changes that are important to their own quality of life?" As is the case with human health, the gradient in environmental systems may be extensive between robust health and collapse in some cases, but an abrupt transition from health to collapse may occur in others. By reviewing information available about the behavior of ecosystems under stress,

Table 2 Responses expected in stressed ecosystems*Energetics*

Community respiration increases
Gross production/community respiration (P/R) becomes unbalanced
Maintenance cost increase; gross production/standing crop biomass (P/B) and community respiration/standing crop biomass (R/B) ratios increase
Importance of auxiliary energy increases
Exported or unused primary production increases
Nutrient cycling
Nutrient turnover increases
Horizontal transport increases, vertical cycling of nutrients decreases
Nutrient loss increases
Community structure
Proportion of r -strategist increases
Size of organisms decreases
Life spans of organisms or parts decrease
Food chains shorten
Species diversity decreases, dominance increases, redundancy declines
General system-level trends
Ecosystems become more open
Autogenic successional trends reverse
Efficiency of resource use decreases
Parasitism increases, mutualism decreases
Functional properties more robust than structural properties

Source: Reproduced from Odum EP (1985) Trends expected in stressed ecosystems. *Bio Science* 35: 419–422, with permission from Jstor.

several researchers have tried to outline general ways in which ecosystems respond to various types of stress (Barrett *et al.*, 1976; Odum, 1985; Rapport *et al.*, 1985; Schindler, 1990). An environmental general stress syndrome at the ecosystem level may include the features listed in Table 2; however, experience is continually modifying this list. These efforts to derive an environmental stress syndrome are important because they define a progression of impact in which some minor changes precede other more serious ones. By recognizing changes early in the progression of impact, remediation could begin and crises could be averted. However, the challenge of finding one general description for widely varying systems, challenged by widely varying combinations of stress, is daunting.

Stressed ecosystems often recover once the stress has been removed. However, sometimes human assistance is required, and this process is called ecological restoration or rehabilitation. Restoration has as its goal the return of an ecosystem to a close approximation of its condition prior to the stress and the recreation of a functioning, self-regulating system that is integrated into the ecological landscape in which it occurs. The practice of ecological restoration often involves the reconstruction of physical conditions present prior to the stress, chemical cleanup, and biological manipulation, including revegetation and the reintroduction of native species.

Stress Assessments

Studies of environmental stress can have different purposes. In some studies, the purpose is accounting, i.e., what is the existing condition of this biological system? This question

can be important for the purposes of disclosure, national environmental accounting, prioritization, and remediation. Studies of environmental stress can also be used for prediction, i.e., will this action cause a problem or which action is better? Predictive studies are used to register chemicals, rank risks, design processes, etc. Another distinct purpose for studies of environmental stress is to provide early warning of conditions that, if left unchecked, will result in significant damage to human quality of life. By detecting damage before it is of a magnitude that is unacceptable, crises can be averted.

Appraisal

Studies of environmental stress can assess the condition of biological systems that exist at a particular point in time. When repeated over time, trends in condition can be assessed. Appraising the condition of a biological system can confirm that environmental quality is adequate or can serve to define an existing environmental problem. Many countries are undertaking a national accounting of the health of their ecological systems. For example, the Canadian State of the Environment Reports and the Environmental Monitoring and Assessment Program in the US measure the condition of rivers, lakes, forests, wetlands, arid lands, and agroecosystems. Although some of these programs measure common sources of environmental stress, as well as biological response, others focus solely on response. Once a problem is found, additional studies to diagnose the problem would include measures of environmental stress.

Prediction

Often, the easiest way to maintain environmental quality is to prevent damage before it occurs. This strategy requires prediction of the future. Such predictions can come from observations of the effects of similar stress on similar systems or from extrapolations or models from the effects of dissimilar stresses or the effects on dissimilar systems.

The ability to extrapolate the measured effects of environmental stress at one level to consequences at a higher hierarchical level depends on the use of mechanistic models that describe the interaction of component parts. The model is then calibrated, i.e., compared to observed behavior of a system under environmental stress and adjusted to maximize the accuracy of its predictions. Currently, there are a few calibrated models for large-scale predictions. Also, it is unlikely that calibrated models will be available for some processes because their spatial and temporal scales make testing impractical or unethical. All hypotheses and theories are more readily accepted if they have withstood rigorous testing. Predictions of environmental stress are no exception. As a general rule, multiple lines of evidence published in peer-reviewed professional journals whose contents have been reviewed by respected professionals result in acceptance both by the person carrying out research on environmental stress and by mainstream science. Generally, validation occurs in two primary ways: (1) a designed test of a hypothesis derived from a theory, especially by those having nothing to do with its development, and (2) consilience with other well-accepted and tested

theories. Predictions of environmental stress are particularly likely to be challenged outside the scientific community because taking precautionary measures to avoid conditions estimated to cause stress often requires changing societal and industrial practices and sometimes engenders costs. Environmental stress associated with global warming is a good illustrative example. Limiting greenhouse gases in the atmosphere will affect the lives of almost every person on the planet, as would significant global warming. In this case, the entire planet is the experimental unit, making designed tests of impact at the same hierarchical level as that of the environmental problem impossible since there is no control planet available. As a consequence, much uncertainty about the probable effect of increased greenhouse gases will persist. However, management decisions about such gases must be made and must be based on the best available information; managers must act even though there is uncertainty accompanying any estimate of risk. Fortunately, most forms of environmental stress, such as exposure to potential toxicants, are much more easily validated.

Early Warning

Monitoring is a systematic and orderly gathering of data to ensure that previously established quality control conditions are being met. Biomonitoring applies this activity to the detection of environmental stress. In this case, the goal is to provide an early warning that unacceptable levels of environmental stress have occurred. As is the case in an intensive care room in a hospital when heart and respiration rates are monitored and unacceptable conditions are detected, an immediate action is mandatory. In any form of quality control, the more rapidly the information becomes available, the more quickly corrective action can be taken. Extensive use of information technology has made complete automation of some monitoring systems, including triggering the remedial action, possible. However, in the absence of carefully selected goals and objectives related to the decisions to be made, it can also generate huge amounts of unnecessary and inappropriate data.

Setting the corrective action threshold low to ensure early detection of deleterious change seems prudent, but it can also produce false-positive readings. A false positive is an indication that some deleterious effect has occurred when in fact none has occurred. Emergency team response to eliminate stress can be quite expensive and unpopular with management. False positives are usually most numerous when monitoring is in the early developmental stages and decrease substantially as experience is gained. Avoiding false positives by setting the action threshold well beyond the response threshold will probably result in false negatives. A false negative is information that no deleterious effects have occurred when in fact some have occurred. Thus, ecosystem damage occurs because no corrective action alert is produced. These false signals are clearly a matter of prime importance in the design of all monitoring systems. The dilemma is that one wishes to detect environmental stress at the earliest possible moment, but this may result in false signals since sensitive end points are often highly variable.

The Biospheric Life Support System

Earth is now in its sixth biosphere. This sixth biosphere provides unique conditions in which the genus *Homo*, including *Homo sapiens*, evolved and flourished. The biosphere also provides the resources on which the human economy is based. In terms of biospheric function, a species must not only be present but present in sufficient numbers to be effective ecologically. The present biosphere has already suffered from a substantial loss of species due to both extinction and biotic impoverishment. The tipping point for the present biosphere is unknown. Changes caused by passing a tipping point are irreversible; consequently, prudence dictates avoiding such a tipping point.

Future Trends

In view of unprecedented growth in human population and the desire to raise the standard of living above the subsistence level for most of the world's people, there are new challenges for those studying environmental stress. The level of environmental stress from food production and energy usage may increase. Simultaneously, there is a great pressure to increase food production to feed the increasing human population, and the need to protect intact biological systems and ensure their robust functioning so that they can continue to provide necessary ecosystem services will become more pressing. Some approaches to these problems are of great interest.

The [World Commission on Environment and Development \(1987\)](#) of the US published *Our Common Future*, which focuses attention on the future condition of the planet, arguably more so than any publication that preceded it. The commission defined sustainable development as

development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

This presents a curious combination of words because “sustain” means to continue and “development” is usually associated with growth. However, infinite growth on a finite planet is clearly not possible.

In December 1989, the General Assembly of the United Nations (UN) attempted to address the problems identified in *Our Common Future* ([World Commission on Environment and Development, 1987](#)) by organizing the UN Conference on Environment and Development (popularly known as the Earth Summit), which was held in Rio de Janeiro in June 1992. This conference resulted in a heightened awareness of the interrelatedness of environmental degradation and stress, population development, and depletion of natural resources. Previously, all had been viewed as separate problems, but now attempts are being made to address them as an interactive system. The resulting Rio Declaration on Environment and Development endorsed the following principles: (1) Nations should not cause damage to the environment of other states and areas beyond their borders; (2) eradicating poverty and reducing disparities in worldwide standards of living are indispensable requirements for sustainable development; (3)

the polluter, in principle, should pay the cost of pollution; (4) states should discourage or prevent trans-boundary movements of activities and the substances that endanger health or environment; and (5) scientific uncertainty should not be a reason for postponing urgent measures to prevent environmental degradation.

Sustainable use of the planet will not be possible if excessive environmental stress impairs the ecological life support system that provides necessary ecosystem services. As a consequence, keeping environmental stress at tolerable levels has a direct bearing on the quality of life for humans. Events beyond human control, such as a large extraterrestrial object striking earth, make it impossible to guarantee that reducing environmental stress will ensure sustainability.

The theory of "weak sustainability" asserts that human society is sustainable provided that the aggregate stock of manufactured and natural assets is not decreasing. Thus, the loss of the whaling industry would not impair sustainability if the proceeds of liquidation are invested in industries of comparable income-producing potential. [Pearce and Atkinson \(1993\)](#) dispute the assumption that natural and human-made capital are sustainable in this context. They assert that strong sustainability requires that natural capital stocks be held constant, independently of the human-made capital. A weak sustainability scenario would permit considerably more environmental stress than a strong sustainability scenario. Conventional monetary analyses are biased against strong sustainability. For example, at a discount rate of 5%, the current value of ecological services for an American life span (about 76 years) from the present on is approximately 2.5 ¢. Using this approach, the farther into the future one projects, the less valuable natural systems appear, thus diminishing the significance of environmental stress.

Reducing environmental stress requires the cooperation of the entire society. One of the most important components is the industrial system. Fortunately, the field of industrial ecology (IE) is developing worldwide ([Hawken, 1993](#)). The goal of IE is to reduce environmental stress at all stages: (1) extraction of raw materials, (2) processing, (3) disposal of manufacturing wastes, (4) packaging, and (5) reincorporation into the environment at the end of the product's life in a nonstressful way, ideally in a way that enhances ecological integrity. IE's primary goals are to (1) reuse materials as much as possible, (2) reduce energy consumption per unit produced, and (3)

design both processes and products so that they can be re-incorporated into the environment with minimal stress. Books such as *Engineering within Ecological Constraints* ([Schulze, 1996](#)), which was produced by the National Academy of Engineering, are directed toward achieving this goal.

Glossary

Chlorofluorocarbon (CFC) A type of hydrocarbons that are nonreactive, nonflammable organic molecules in which both chlorine and fluorine atoms replace some of the hydrogen atoms. Use of CFCs is one of the primary causes of stratospheric ozone depletion.

Montreal Protocol A treaty signed by a number of nations to curtail CFC production.

Ozone A form of oxygen in which three atoms of oxygen occur together. Ozone forms a natural layer in the stratosphere that blocks living organisms from harmful ultraviolet radiation from the sun.

Photolyases DNA repair enzymes that repair damage caused by exposure to ultraviolet light.

Ultraviolet radiation Radiation with wavelengths shorter than violet light and with more energy.

Properties of Light

Light is a natural phenomenon that allows us to see objects, shapes, and colors. It radiates from the sun, the stars, a flame, or a light bulb. Light encompasses a broad spectrum of radiation that includes gamma rays, ultraviolet (UV) rays, infrared rays, microwaves, and radiowaves (**Figure 1**). These types of radiation are all classified as nonvisible light and consist of the longest and shortest wavelengths and frequencies. A small section of the spectrum is the visible light spectrum. The wavelengths of this region range from 380 to 750 nanometers (nm) and are the only part of the electromagnetic spectrum (**Figure 1**) that can be detected by the human eye. When light shines on an object, some of the light is absorbed and converted to heat; another percentage is scattered or dispersed in various directions; some are transmitted; and the rest may be reflected depending on the material on which the light strikes.

UV Radiation

The electromagnetic spectrum is continuous, but the types of electromagnetic radiation do not begin or end at precise points along the spectrum. For example, red light shades into invisible infrared (below red) radiation and violet light shades into invisible UV (beyond violet) radiation. The sun is the major source of UV radiation for the Earth. UV is responsible for producing suntans and vitamin D in the human body. In

humans, overexposure to UV can lead to serious and sometimes irreparable harm. It can cause mutations in cellular DNA, which can ultimately lead to significant alterations in cells, the main cause of cancer. Other damaging effects of UV include premature aging, blindness, and sterilization. UV radiation also has the ability to kill microorganisms, plants, and animals.

UV can be divided into four wave bands. These are vacuum UV (<200 nm), UV-C (200–280 nm), UV-B (280–315 nm), and UV-A (315–400 nm). At the earth's surface, vacuum UV and UV-C are not present because of their absorption by various gases such as oxygen and ozone. The formation of atmospheric oxygen and a stratospheric ozone layer was essential for the evolution of life on earth. The ozone layer shields the terrestrial surface from harmful UV radiation. Unfortunately, through anthropogenic emissions of chlorofluorocarbons (CFCs) and other gases, the ozone layer has been adversely affected. It has thinned and has developed "holes" in polar regions. Thus, there is potential for increased UV radiation hitting the earth's surface.

The ozone hole over Antarctica has dramatically increased since its discovery in the 1970s. At midlatitudes, ozone levels have also continued to decrease. Stratospheric ozone levels are at their lowest point since measurements began, so the current UV-B radiation levels are thought to be close to the maximum. Global ozone measurements from satellites from 1979 to 1993 show increases in UV-B radiation at high and midlatitudes of both hemispheres, but only small changes in the tropics. These estimates assume that cloud cover and pollution

Figure 1 The electromagnetic spectrum. Visible light and other forms of electromagnetic energy radiate through space as waves of various lengths. Reprinted from figure 10.5 in Campbell NA (1996) *Biology*, 4th edn, with permission from Benjamin Cummings.

have remained constant over the years. Increases in surface erythema (sunburning) UV radiation relative to values obtained in the 1970s are estimated to be about: 7% at Northern Hemisphere midlatitudes in winter and spring and 4% in summer and fall; 6% at Southern Hemisphere midlatitudes throughout the year; 130% in the Antarctic in spring; and 22% in the Arctic in spring. The resulting increases in UV radiation threaten humans, animals, plants, and microorganisms in both terrestrial and aquatic ecosystems.

The pioneering work of Rowland and Molina showing that CFCs were responsible for the decrease of stratospheric ozone caused considerable concern among atmospheric and environmental scientists. They reasoned that CFCs in the stratosphere would be subjected to intense UV radiation, which would break them apart, releasing free chlorine atoms.

All the chlorine of a CFC molecule would eventually be released due to further photochemical breakdown. The free chlorine atoms could then damage stratospheric ozone, forming chlorine monoxide (ClO) and molecular oxygen. Molecules of ClO can react to release more chlorine and an oxygen molecule.

These reactions are part of the chlorine cycle because of the continuous regeneration of chlorine as it reacts with ozone. Chlorine is the catalyst in the reaction because it promotes the chemical reaction without being used up. Because chlorine can last for 40–100 years, every chlorine atom in the atmosphere can potentially break down 100,000 molecules of ozone. CFCs are especially damaging because they are transport agents that constantly move chlorine atoms into the stratosphere and because chlorine atoms are removed from the stratosphere very slowly.

By 1978, most Scandinavian countries and the US banned the use of CFCs in spray cans. In 1983, most European countries proposed a voluntary reduction in the use of CFCs. As a result of increasing concern over the effects of ozone depletion, an international agreement was signed to reduce and eventually eliminate certain anthropogenic ozone-destroying substances. A treaty, known as "The Montreal Protocol," was signed by a number of nations on 16

September 1987, in Montreal, Quebec. The protocol which consisted of a plan that would dramatically cut CFC production was recognized as the first worldwide effort to solve a massive environmental problem. Since 1987, more than 150 countries signed the agreement to phase out all the uses of CFCs by 2000. Despite this agreement, the worsening environmental news about CFCs and ozone depletion in the 1990s led certain nations to adopt stricter measures, limiting CFC production.

Several industrial companies have developed CFC substitutes. CFCs and several other chemicals that contribute to ozone depletion have been phased out in the US and several other countries. Nevertheless, existing stockpiles of these chemicals can be used until the deadline. Moreover, developing countries are on a different time course and will phase out CFCs by 2006. Unfortunately, CFCs are very stable and estimates suggest that those in use today will continue to deplete stratospheric ozone for 50–150 years. Atmospheric scientists believe that the Antarctic ozone hole will reappear each year until about 2050. However, because of the Montreal Protocol and other measures to limit ozone-depleting substances, there is some optimism about ozone depletion being curtailed.

Bromine (Br) is another important source of ozone depletion. Br is present in smaller quantities than chlorine but is more destructive on an atom-to-atom basis. The largest source of Br is methyl bromide, which comes naturally from the oceans and wildfires. However, a large portion of methyl bromide is human-made and is used as a fumigant. Another important source of bromine is fire extinguishers. Like CFCs, methyl bromide has a long atmospheric lifetime (approximately 72 years). Regulations on the use of methyl bromide are being debated.

Measurement of Environmental UV Radiation

Although significant advances have been made, measuring UV radiation is difficult. There are significant differences in how

various devices measure UV radiation. Moreover, there are a number of factors that affect UV radiation. For example, there are geographical and seasonal variations in UV. Thus, recent studies have confirmed that there are generally higher UV-B levels at lower latitudes in the US. Other measurements confirm latitudinal differences in Europe, Asia, and New Zealand.

Spectral measurements show higher summer values of both UV-A and UV-B radiation in New Zealand and Australia compared with Germany due to the yearly cycle of the sun–Earth distance and due to the lower stratospheric ozone levels in the southern hemisphere and higher air pollution levels in Germany. Additional UV data are being accumulated for midlatitudes, and eventually, a more complete picture of the UV situation at these latitudes will emerge.

Cloud cover also affects UV-B radiation levels on the earth's surface. Data from several locations in the US suggest that the monthly average UV levels are reduced by 10–50% by cloud cover, depending on the location and season. Aerosols (small particles suspended in the air) may also reduce UV levels in polluted areas. The magnitude of this effect is highly variable and may depend on the number of particles and their chemical and physical composition.

UV levels are expected to increase with increasing surface elevation above sea level due to a thinner atmosphere overhead. Measurements in a remote area of Chile, for example, showed increases of 4–10% per km in elevation. Other locations showed larger vertical gradients of up to 40% per km near Santiago, Chile, and 9–23% per km in the Swiss Alps.

Because of the high spatial and temporal variability of surface UV radiation and the difficulty of maintaining calibration within instruments, it is difficult to provide global UV climatology and represent long-term UV trends based on ground monitoring stations alone. However, satellite-based measurements can provide global coverage and continuous long-term monitoring. Yet, it is difficult to use remote satellite data in an attempt to estimate UV levels from specific microhabitats on earth. The derivation of surface UV irradiance from satellites is indirect because satellites detect radiation reflected by the atmosphere and the surface of the earth. The use of radiative transfer models is necessary to relate transmission, reflection, and atmospheric absorption. These models have been useful in showing general changes in UV radiation reaching the surface, and are computed for clear skies using satellite ozone measurements.

Effects of UV Radiation on Biological Systems

DNA Repair

At the terrestrial surface, most UV radiation of biological concern is in the 280–315 nm (UV-B) band. UV light induces a variety of photoproducts in DNA. UV photoproducts impede gene expression by blocking transcription, and they can cause cell death or mutagenesis. There are a number of responses to DNA damage by living cells. The two fundamental processes for repairing UV-induced DNA damage are direct reversal of DNA damage or its excision. These processes can be explained by analogy. If we consider a rope with a knot, we can either undo the knot (direct reversal of damage) or cut the knot out

and replace the rope with a new piece (excision of the knot). This descriptive analogy roughly represents how photo-reactivating enzyme, photolyase, and excision repair, respectively, work to undo DNA damage.

Thus, harmful photoproducts can be removed by photo-reactivating enzyme, photolyase. In some species, this is the most important mechanism for DNA repair. In excision repair, when DNA molecules are damaged, a segment of the strand of DNA containing the damage is cut out by one repair enzyme, and the resulting gap is filled in with nucleotides (building blocks of DNA) properly paired with nucleotides in the undamaged strand.

Effects of Increased Solar UV Radiation on Terrestrial Plants

Obviously, it is extremely important to understand the effects of increasing solar UV radiation on terrestrial plants. Plants comprise most of the living matter in terrestrial ecosystems. Damage to plants within natural ecosystems and in agricultural systems can have far-reaching consequences on other organisms, including humans.

Both the physiological and developmental processes of plants are affected by UV-B radiation. Several studies have shown that some plant species in greenhouses, growth chambers, and in the field have reduced growth and leaf area under close to ambient UV-B conditions compared with plants grown under reduced UV-B levels. Increased UV-B radiation may greatly affect photosynthesis. In certain species, such as soybean, sunflower, and corn seedlings, solar UV-B radiation reduced photosynthesis by about 15% when a 12% ozone depletion was simulated. UV-B radiation can also alter the time of flowering and the number of flowers in certain species. Alteration of flowering time can have a severe impact on plants because pollinator availability may be subsequently affected. Anther walls can absorb more than 98% of incident UV-B radiation, and pollen walls contain UV-B-absorbing compounds, providing some protection from the negative effects of UV-B. However, after the transfer to the stigma, pollen may be directly exposed to UV-B radiation. Several experimental studies using Mylar or glass filters that shielded plants from UV-B radiation showed that flowering was enhanced under these regimes. Different studies have shown the different effects of UV-B on flowering in various species. For example, flowering was inhibited in plants such as *Melilotus* and *Trifolium*, but *Zea mays* and *Sorghum* were not affected. In sexually reproducing populations of a desert plant, the effects of UV-B radiation on growth and biomass seemed to accumulate in subsequent generations that were exposed to UV-B radiation. Thus, the effects of exposure to UV-B radiation may be amplified. Even roots of plants can be affected by elevated UV-B radiation. For example, the microorganisms associated with the roots of sugar maple trees were altered when the shoots of the trees were exposed to UV-B radiation.

The yields of certain crop plants may be significantly affected by increases in UV-B radiation. The available data on the effects of UV-B radiation on yield illustrate significant interspecific variability and, also, variability among cultivars complicated by differences in how the experiments were

performed. Nevertheless, some species and certain cultivars seem to be more tolerant to UV-B than others. For example, results from greenhouse and field tests suggest that the soybean cultivar "Forrest" was more tolerant to UV-B radiation than the cultivar "Shore." A study of 10 crop species in Florida showed that under UV-B radiation, yields were reduced by 5–90% in half of them, including wheat (5% reduction), potato (21% reduction), and squash (90% reduction). In this study, rice, peanut, and corn were not affected.

Several studies have shown that plant susceptibility to herbivores and pathogens is altered by UV-B radiation. For example, a number of studies have shown that ambient UV-B radiation can reduce insect herbivory of agricultural pests and native plants. Supplementation of solar UV-B radiation in field studies can reduce the population of herbivorous insects in certain systems. It is unclear why changes in herbivory occur. It is possible that the secondary compound plant defenses may be altered, or that UV-B directly affects the herbivores. However, most of these studies suggest that the changes in insect herbivory are due to changes in host plant tissues.

Experiments conducted in greenhouses and in the laboratory suggest that viral and fungal pathogens react differently to UV-B radiation. Some studies indicate that UV-B radiation promotes the severity of disease, whereas other studies indicate a reduction in infection severity. For example, cucumber plants first exposed to UV-B radiation were more susceptible to subsequent infection by fungal pathogens. However, if exposed to UV-B radiation after infection, there was no effect on the severity of the disease. Other studies have shown that when UV-B radiation is removed, there is increased incidence of fungal infection.

Because there are differences in tolerance to UV-B radiation in different species, it is suggested that a reduction of primary productivity in one plant species may lead to an increase in primary productivity in another more UV-B-tolerant species. Thus, it is possible that the overall productivity within an ecosystem may change, even if species composition is unaffected. Even if the plant species composition does not change, individual plant form may change, which could affect how these plants compete for sunlight, moisture, and nutrients. This could lead to significant changes in the overall characteristics of ecosystems.

Effects of Radiation on Aquatic Systems

The attenuation of solar radiation on the water column is dependent on a variety of factors. The transparency of the water to UV radiation is dependent on many characteristics of the water. For example, there can be highly turbid coastal waters that do not allow much UV-B to penetrate very deeply. In comparison, some ocean waters are clear enough so that the UV-B penetration can be for dozens of meters. In the Antarctic, 1% of the solar UV-B hitting the surface has been measured at a depth of 65 m. Solar UV-B has been shown to degrade dissolved organic carbon (DOC). Increased breakdown of DOC and subsequent consumption by bacteria increases the UV-B penetration in the water column.

Across life histories, trophic groups, habitats, and experimental venues, UV-B negatively affects the growth and survival

of aquatic organisms. A meta-analysis investigating the effects of UV-B across life stages found that UV-B had a greater negative effect on embryonic growth compared with growth at the larval stages. However, in amphibians, the larval stage experiences greater mortality than the embryonic stage. Additionally, across taxonomic groups, protozoans appear to undergo the greatest reduction in growth rates compared with animals or plants.

Plankton

Globally, phytoplankton is the most important producer in aquatic ecosystems. Thus, damage to phytoplankton populations will affect higher trophic levels. A number of studies in a variety of aquatic ecosystems have shown that UV-B radiation affects the growth, survival, and distribution of phytoplankton. Phytoplankton exist on the top layers of the oceans and freshwater aquatic systems. The Antarctic is especially productive in phytoplankton, and the region is significantly impacted by UV-B because of the Antarctic ozone hole. Therefore, a number of studies on the effects of UV-B on phytoplankton have been conducted in that region. In certain experiments, productivity was two to four times higher in tanks where UV-A and UV-B were excluded. Pigmentation was also affected. *In situ* incubations of natural phytoplankton assemblages in the Antarctic waters indicated that photosynthesis was impaired by about 5% under the ozone hole. A similar result was found in the tropics. Screening of most UV <378 nm resulted in a 10–20% increase in photosynthesis. However, no significant decrease in stratospheric ozone have been observed in the tropics.

Many phytoplankton can actively move to different positions within a particular habitat. They may do this via flagella, cilia, or by utilizing buoyancy to adjust their position in the water column. Various chemical, magnetic, light, and gravity cues influence movement so that plankton can maintain specific positions within the water column. To cope with constantly changing environmental conditions, these organisms must constantly adjust their positions. If UV radiation affects motility, or the ability of phytoplankton to respond to external cues, this may negatively affect their growth and survival. There is growing evidence that many phytoplankton species are under stress from ambient levels of UV radiation.

Macroalgae and Seagrasses

In contrast to the motile phytoplankton, macroalgae and seagrasses are attached to their growing sites. Thus, they are restricted to certain depth zones. It is thought that this zonation is caused, at least in part, due to limits of visible light penetration at various depths. Some species may be more tolerant to solar radiation than others. Thus, increased levels of UV-B radiation may expose algae and seagrasses to levels that they have not encountered, perhaps affecting growth and photosynthesis. Several studies have shown that UV-B radiation inhibits photosynthesis in many of the red, brown, and green algae. Deep water algae were the most affected, whereas intertidal algae were the least sensitive.

The DNA of algae appears to be poorly shielded when compared to higher plants. For example, doses of UV-C radiation (at 254 nm) necessary to kill leaves of higher plants appear to be about four orders of magnitude greater than that

necessary to kill highly resistant algae. Flavenoids, highly effective UV-screening compounds found in higher plants, have not been found in algae. In higher plants, flavenoids exist in high enough concentrations in the epidermis of leaves so that in combination with cuticle waxes and other cell-wall components, the incidence of UV radiation is reduced by one or two orders of magnitude. However, algae do produce other UV-absorbing substances, including a yellow protein-carotenoid complex in some species and other substances that afford some protection from UV radiation.

An experimental study conducted in Canada illustrates how ecosystems may have complex responses to increased solar UV-B radiation. Solar UV radiation can reduce photosynthesis and growth in bottom-dwelling algal communities in shallow freshwater. However, in this study, it was observed that greater amounts of algae were accumulated in UV-exposed habitats than in UV-protected environments. UV-A and UV-B radiation inhibited insects that feed on algae. Because larval algal consumers are more sensitive to UV radiation than algae, algal abundance increased.

Invertebrates

Sunlight can be lethal to a wide variety of marine and freshwater plankton exposed for just a few hours or a few days. Mortality rates are usually lower in zooplankton that contain photoprotective compounds including pigments derived from dietary plant carotenoids, melanin, and substances known as mycosporine-like amino acids that gets absorbed in the UV-A and UV-B range. The presence of these photoprotective compounds suggests that there is significant selection pressure associated with the harmful effects of UV radiation.

A number of experimental studies have shown that natural levels of UV radiation are lethal to zooplankton. For example, one study in Pennsylvania showed that zooplankton communities exposed to ambient levels of UV-B for 3 days experienced significant mortality when they were not shielded from UV-B radiation. However, mortality was significant only in an oligotrophic lake, not in an eutrophic lake where light penetration is not as high.

Marine invertebrates differ considerably in their sensitivity to UV-B radiation. For example, while one species of crustacean may suffer about 50% mortality at current levels of ambient UV-B radiation at the sea surface, some shrimp can tolerate irradiances higher than those predicted for a 16% ozone depletion. Bottom-dwelling invertebrates of the ocean may also be affected by UV-B radiation. For example, cleavage in sea urchins is impaired by UV radiation. Marine organisms associated with coral reefs, such as sponges, bryozoans, and tunicates, are also adversely affected by UV-B radiation.

Corals are affected by UV radiation in a number of ways. Depending on the species and the particular ecosystem, a number of studies illustrate that UV radiation can cause death, inhibit growth, and contribute to coral bleaching. Bleaching, a well-recognized phenomenon, occurs principally via the loss or expulsion of symbiotic algae from the coral host tissue. When the algae are lost, the coral loses its characteristic color and the remaining white polyp is most noticeable. Although a number of events, including elevated seawater temperature and heavy rains, can contribute to bleaching, there is some

evidence that UV radiation may also play a role in certain bleaching events.

UV radiation can inhibit photosynthesis in symbiotic algae. UV radiation affects respiration among corals and their symbiotic algae, but not in a consistent way. In some species, respiration increases under UV radiation, whereas in other species it may decrease and in others respiration may be unaffected.

UV radiation inhibits the growth of symbiotic algae in culture. Reproduction in corals may be affected by UV-B radiation. Broadcast spawning at night, a nearly universal phenomenon among many reef invertebrates and corals, might be related to avoiding UV-induced DNA damage as well as to reducing predation. In at least one study, it was observed that the larvae of reef corals from shallow water were more resistant to UV-B radiation than those from deeper water.

In the Antarctic, a number of marine invertebrates sustain UV-induced DNA damage. These include worms and crustaceans. Krill, copepods, and gelatinous zooplankton generally have transparent eggs, larvae, or adult stages that are pelagic and planktonic, and are often found in surface water for several months. Thus, these species are especially vulnerable to DNA damage from elevated UV-B exposure. These species are important components of the ecosystem, and damage to them could have significant consequences on the ecosystem.

Fishes and Amphibians

A study of Antarctic zooplankton, including larval fish, showed that they sustain DNA damage during periods of increased UV-B flux. Fish larvae in Antarctic marine ecosystems sustained UV-B-induced DNA damage greater than the lethal limit determined for Antarctic diatoms, and comparable to the lethal limit of damage for cultured goldfish cells. DNA damage has been shown to be especially correlated with daily UV-B flux in icefish eggs. Icefish larvae, however, showed patterns of DNA damage that correlated less significantly with daily UV-B flux. Antarctic fish appear to primarily use photolyase to remove harmful UV-B-induced photoproducts.

Other fish species may also be affected by UV-B radiation. For example, in the Arctic ecosystem, many economically important fish species, including cod, pollock, herring, and salmon, spawn in open shallow water and are subjected to increased solar UV-B radiation. Because many of their eggs are found near the surface, it is possible that marine fish productivity could decline in this region due to increased UV-B radiation. At this point in time, however, it is difficult to assess the impact of UV-B radiation on Arctic fish productivity. However, a laboratory experiment demonstrated that salmon exposed to UV-B radiation are more prone to fungal infections and skin lesions.

Several laboratory studies have shown that UV radiation affects the growth, development, and hatching success of certain amphibian species. These studies have shown that under simulated UV light of various intensities, amphibians may develop skin lesions, edema, eye damage, curvature of the body, and behavioral abnormalities. Under relatively low-level but prolonged doses of UV radiation, the mortality of embryos increases compared with controls that are shielded from UV radiation.

Amphibian Declines and UV Radiation

Amphibian populations are undergoing a serious decline in various regions of the world. Unfortunately, the causes for amphibian population declines have been difficult to assess. Much of the information on amphibian declines comes from observational or anecdotal accounts. Hypothesized causes for the declines include habitat destruction (the most obvious cause), climate change, pathogens, introduced exotic species, pollution, and increased UV radiation. These agents may act alone or in combination to contribute to the decline of amphibian populations.

The diversity of locations where amphibian populations have declined prompted consideration of atmospheric factors such as increased UV irradiance associated with depletion of stratospheric ozone. Several investigators have used field experiments to examine the potential role of UV-B radiation in amphibian population declines by measuring the mortality of embryos that were shielded from UV radiation compared with the embryos that were unshielded. Continuous high mortality in early life stages may ultimately contribute to a decline in the population level.

Field experiments from North America, Europe, and Australia show that ambient UV-B damages the embryos of certain amphibian species but not others. Results of these experiments by several different investigators strongly indicate that the hatching success of at least nine species of amphibians, from widely separated locales, is reduced under ambient UV-B radiation. This includes a taxonomically diverse group of two frog species, one toad species, two salamander species, and a newt from North America; two frog species from Australia; and a toad species from Europe. Some of these species are found in montane areas, and others are found at sea level. A key characteristic shared by these species is that they often lay their eggs in shallow water, where they are exposed to solar radiation.

Hatching success of several other amphibian species in North America, Australia, and Europe was not affected by UV-B radiation. This is not surprising because several studies have demonstrated differential sensitivity of amphibians to various abiotic factors. There may be variation in response to UV-B radiation, perhaps even within a species, at different locations. For example, embryos of western toads in Oregon are sensitive to ambient levels of UV-B, while those of a different subspecies in Colorado are unaffected.

Based on a limited sample, there is a correlation between resistance to UV-B and the activity of photoreactivating enzyme, photolyase. Species with the highest photolyase activities seem to be more resistant to UV-B radiation. Furthermore, of the species examined, frogs and toads generally show more photolyase activity than salamanders. It is also possible that nuclear excision repair is also being used to counter UV-induced DNA damage, but this has not been measured in amphibian species taken from the wild.

In nature, more than one environmental agent may affect an animal as it develops. This also seems true for amphibians developing at their natural field sites. Field experiments have been conducted to examine at least three factors that seem to interact synergistically with UV-B: a pathogenic fungus, low pH, and fluoranthene, a polycyclic aromatic hydrocarbon that may pollute aquatic environments impacted by petroleum contamination. A meta-analysis investigating the combined

effects of UV-B with pH, contaminants, and disease found that UV-B radiation interacted synergistically with other stressors, resulting in greater-than-additive effects on survival. In certain combinations with UV radiation, these three agents increase mortality to levels greater than that contributed by UV radiation alone.

Obviously, UV-B cannot be regarded as contributing to all amphibian population declines. For example, UV-B radiation is unlikely to contribute to mortality in amphibians that are primarily nocturnal, live under dense forest canopies and lay eggs hidden from solar radiation, or have high photolyase activities.

Amphibian Deformities and UV Radiation

Reports of deformed amphibians have been given wide media attention, with the most common reports of deformities being frogs and toads with extra or missing limbs. Three major agents are being examined: pesticides, UV radiation, and parasitic trematode infection. However, only limited data are available on this subject based on experimental work. One laboratory study of northern leopard frogs showed that on exposure to 24 h of simulated ambient UV light, frogs developed hindlimb malformations. It remains unclear as to whether UV radiation can cause extra limbs in wild amphibian species. However, other deformities in wild species have been observed. These include edema, curvature of the spine, and lesions in larvae and newly metamorphosed amphibians. One report showed severe retinal abnormalities consistent with UV damage in a basking frog species.

Effects of UV Radiation on Biogeochemical Cycles

The effects of increased UV-B radiation on biogeochemical processes may be complex. For example, increased UV-B radiation may affect the magnitude and direction of trace gas on emissions and mineral nutrient cycling in terrestrial systems. Moreover, the effects on these processes may be species specific and may vary in different ecosystems. Increased UV-B radiation may alter the chemical composition of plant tissue, the photodegradation (breakdown) of dead plant matter, the release of carbon monoxide, and the activity of microbial decomposers, and nitrogen-fixing organisms.

In aquatic ecosystems, increased UV-B radiation may affect the processes that produce organic matter and the processes that degrade organic matter. There may be photodegradation of dissolved organic matter, which may lead to the production of organic acids and ammonium. Photoinhibition of surface aquatic organisms may also affect biogeochemical processes.

The potential effects of increased UV-B radiation on terrestrial and aquatic carbon, nitrogen, sulfur, oxygen, and metal cycles have been explored in a number of studies. These effects and similar effects on biogeochemical cycles in the atmosphere may aid or help impede the buildup of greenhouse gases and aerosols in the atmosphere.

Effects of UV Radiation on Humans

UV-B radiation does not penetrate deep into the body because most of it is absorbed in the superficial tissue layers. Therefore,

much of the UV radiation affects the skin and eyes. However, there are also systemic effects. UV-B is the main cause of sunburn and tanning and the formation of vitamin D₃ in the skin. UV-B also affects the immune system. UV-B can cause snowblindness and is a significant factor causing cataracts. It also contributes significantly to the aging of the skin and the eyes and is effective in causing skin cancer.

Eyes

Photokeratitis is the effect most attributable to exposure to UV radiation. It is similar in effect to a sunburn and often occurs after short-term exposure to UV radiation. The eyeball becomes inflamed and reddens, often accompanied by pain and photophobia (fear of light). This is frequently diagnosed in skiers as snowblindness.

Exposure of the eye to UV radiation can also have effects on the cornea, contributing to degeneration of its fibrous layer. Under certain conditions, exposure to UV radiation can cause an outgrowth of the outermost mucous layer over the cornea, resulting in the loss of transparency. Squamous cell carcinoma (SCC) of the cornea, a malignant neoplasm, can also be found after exposure to solar radiation. These diseases are associated with outdoor living or working near areas of high reflectance (e.g., near water, concrete, and sand).

Cataracts are the leading cause of blindness in the world. They are characterized by a gradual loss in the transparency of the lens of the eye due to oxidized lens proteins. This can lead to blindness unless the affected lens are removed. There is a correlation between certain types of cataracts and exposure to UV-B radiation. Several studies have suggested that the relative risk associated with increased exposure to sunlight and cortical cataracts (those that develop in the outer layer of lens protein) is between about one- and threefold. One model suggests that a sustained 10% loss of ozone worldwide would lead to an additional 30,000 blind people per year.

Sunburn

Sunburn is the most common effect of exposure to UV radiation. This results in the reddening of the skin and possibly blistering. Sensitivity to sunburn and tanning varies with pigmentation. Heavily pigmented individuals are less sensitive to sunburning than less heavily pigmented individuals. There are various categories with regard to sunburn and tanning sensitivity. The most sensitive individuals (skin type I) develop a moderate to severe burn and usually do not tan within an hour of exposure to the summer sun. These persons usually have very fair freckled skin, red or blond hair, and blue eyes. The most resistant individuals (skin type VI) are darkly pigmented and become more pigmented after exposure to the sun.

Photoaging

Exposure to sunlight ages the skin. This is known as photoaging and is characterized by wrinkles, altered skin pigmentation, and an overgrowth of abnormal elastic fibers in the dermis.

Skin Cancer

There are various types of skin cancers. These are basal cell carcinoma (BCC), SCC, and cutaneous melanoma (CM). The carcinomas of the skin are often referred to as the “non-melanoma skin cancers (NMSC).” The NMSCs are clearly correlated with sunlight. They occur primarily in light-skinned individuals, and usually on the areas of the body most exposed to sunlight.

BCC is the predominant form of NMSC in light-skinned individuals. Individuals most susceptible to BCC are those with the lightest skin and a poor tanning ability. The incidence of BCC in light-skinned populations has been increasing in certain regions. Although it was originally thought that cumulative lifetime exposure to sunlight was directly related to developing BCC, recent information suggests that this may not be the case.

SCC is much less common than BCC but is much more common than CM in the US. Epidemiological data suggest that cumulative lifetime exposure to UV is a critical risk factor for developing SCC compared to other types of skin cancers. Several studies found an increase in the risk of developing SCC with incidence of childhood sunburns. However, this may be related to a high level of childhood exposure to sunlight rather than the number of sunburns *per se*.

CM is relatively rare compared with BCC or SCC. It accounts for only about 2–3% of the skin cancers associated with solar radiation, but it also accounts for most of the mortality. Like BCC, there does not seem to be a clear relationship between developing CM and cumulative lifetime exposure to UV radiation. Furthermore, CM often appears on areas of the body that are not the most heavily sun exposed. Several epidemiological studies have shown that exposure to sun during childhood increases the risk of developing CM. An additional risk factor is the appearance of freckles or moles.

Effects on the Immune System

In humans, the skin is the first line of defense against foreign bodies that may threaten an individual's health. Thus, the skin in combination with the immune system helps maintain health against infectious diseases, cancers, and parasites. The skin incorporates a number of cells from the immune system that can mount or influence immune responses to foreign substances. Substances entering the body, such as viruses, have to be “recognized” by the immune system as either “self” or “nonself” (foreign) entities. UV radiation can induce photochemical changes in the skin and potentially alter cell surface proteins that are used to determine “self” from “non self” entities. Thus, UV radiation can be immunosuppressive. The immunosuppressive effects of UV-B radiation can influence the outcome of melanoma and NMSCs, certain infectious diseases, some forms of autoimmunity, and allergy. For example, implants of UV-induced tumors in genetically identical mice are rejected in unexposed hosts but fail to be rejected by UV-exposed mice. UV-B radiation can inhibit local inflammatory responses within UV-irradiated skin. Thus, the response elicited by injection of an antigen into the skin of sensitized individuals may be diminished in UV-irradiated skin.

Some infectious agents can directly be harmed by exposure to UV radiation, whereas others are unaffected. Immunosuppression may also decrease an individual's resistance to certain infectious diseases. In animal models, human infectious diseases have been shown to be influenced by exposure to UV-B radiation. These diseases include herpes, tuberculosis, trichinella, candidiasis, leishmaniasis, listeriosis, and Lyme disease. Effects include suppression of immune responses to the organisms or their antigens, reactivation of latent infections, increased body loads of infectious organisms, decreased resistance to reinfection, and reduced survival. The impact of UV-B exposure on antigen-presenting cells in the skin suggests the possibility that UV-B radiation may exacerbate or ameliorate autoimmune diseases such as Lupus or human immunodeficiency virus (HIV). At the very least, UV-induced immune suppression could affect the course of certain diseases within human populations.

Glossary

Adaptation *One or two of the following:* a beneficial construct produced by an omnipotent being; the process of change established by natural selection; and a biological character that gives increased Darwinian fitness.

Adaptationism The doctrine that all important evolutionary processes are dominated by natural selection, and that all significant biological characters increase an organism's fitness.

Epistasis Interactions between genes at different chromosomal locations in the determination of phenotypic character values.

Fitness Net reproductive output, discounted for any lack of viability.

Genetic drift Accidents of segregation and recombination causing evolutionary genetic change.

Genomics The study of the entire volume of an organism's hereditary information. Methods in population

genomics tend to take one of two forms: (1) surveys of global gene expression in which a subset of the population's RNA is sequenced or otherwise quantified; or (2) surveys of allele frequency in which a sample of the population's DNA is sequenced or otherwise quantified.

Group selection Selection between different populations or sub-populations based on attributes of the entire group, where these attributes usually are either selected against or not favored at the level of individual selection.

Inbreeding The mating of close biological relatives.

Individual selection Selection driven by differences in the net reproduction of individual organisms.

Segregation Allocation of genetic variants ("alleles") to different gametes during sexual reproduction.

Teleology The imputation of goal-directed behavior or structures.

Historical Introduction

Classical Times

The concept of adaptation is older than any scientific concept of evolution, and certainly older than Darwin's theory of natural selection. The founder of academic biology, Aristotle, gave adaptive explanations for many of the features of the living, as well as nonliving, world. Thus the webbed feet of a frog can be said to be "for" efficient swimming, and thus can be explained as an illustration of the universe being well-made. This type of reasoning was commonplace in classical culture, which often assumed some type of benign natural order.

It is significant, however, that adaptive reasoning had its critics even in classical times. Lucretius, one of the most important of classical proto-scientists, was scathing about the wholesale imputation of function to body parts, even when such inferences were regarded as "common sense." Such criticisms of the concept of adaptation have waxed and waned ever since.

Pre-Darwinian Christendom

Biblical theology gave arguments about adaptation a new cast. The assumption that there was a single, benign, omnipotent Creator made the existence of well-constructed organisms a natural inference. From the beneficence of the Creator, each organism must have been given the specific characteristics best suited to its role in the Creation as a whole. Indeed, this

concept of benign, and efficient, creation was extended to physics, especially by Isaac Newton, an avid believer. The orbits of the planets themselves were thereby interpreted as evidence of some type of adaptation, or suitedness, to a divine plan.

This universal adaptation gave rise to some interesting paradoxes for pre-Darwinian scientists. Did the Creator adapt organisms to the physical universe, or was the physical universe created to fit the organisms? Was life on earth based primarily on the chemistry of water and organic molecules because that was the biochemistry that could work on this particular planet? Or was the planet constructed by the Creator to fit the biochemistry that He already had in mind? How could such questions ever be resolved?

The Darwinian Theory of Adaptation

Darwin's theory of evolution by natural selection provided a natural solution to the two problems of what adaptations were and how they came about. On Darwin's theory, selection operating on heritable variation increased the frequency of individuals bearing attributes, which we can call "adaptations," which give them increased fitness. Fitness in turn was to be defined as the net reproductive rate of individual organisms, in the original version of Darwinism. Thus Darwin's theory proposed that the environment drove the evolution of adaptations, by determining the pattern of selection imposed on organisms.

Darwin's theory had a number of novel features for the biology of his time. First, it involved no omnipotent Creator,

beneficently organizing the arrangements of life. Second, there were no inner drives or teleologies shaping the process of organic change to an adaptive end, unlike the scheme of Lamarck and others, who were more influenced by Aristotle than Darwin was. Third, there was no overarching pattern to Darwin's process of evolution, and therefore adaptations might arise higgledy-piggledy, whenever selection made mortality or reproduction hinge on a particular attribute. All of these features made Darwin's new biology of adaptation distasteful to many of the older generation of Victorian biologists, who were highly teleological in their thinking, when not avidly creationist.

Two Common Definitions

The nature of Darwinian theory instilled a large degree of ambiguity in the term adaptation itself. For a creationist, there is no process of adaptation, only the fact of what the Creator made, and its beneficent nature. For the Darwinian, like the Lamarckian, there is necessarily a *process* of adaptation, a process by which adaptation is brought about. Then there is the *product* of adaptation as a process, which is called an adaptation, as well.

There has been some controversy as to which of these basic meanings of the term is really the true one, or the correct one. However, we can follow Ernst Mayr, or Karl Popper for that matter, and reject the need to find any essentially true definition of adaptation. Instead, the two alternative definitions can both be used, as appropriate.

Adaptation as a Process

The concept of adaptation as a process derives from the theory of natural selection. Therefore, a deeper consideration of this incarnation of adaptation requires study of natural selection. One of the basic intuitive expectations that most evolutionary biologists have is that natural selection should lead to the evolution of increased Darwinian fitness. However, this is not universally true. Mutation, segregation, recombination, meiotic drive, and frequency-dependent selection can force natural selection to produce a *decrease* in fitness under some conditions.

Usually this decrease in fitness is temporary. For example, if the heterozygote, at a locus with two alleles, is the most fit genotype, then, when the population is initially composed entirely of heterozygotes, segregation will cause an immediate decrease in fitness. But this effect is confined to the first generation. Subsequent generations will see increasing or stable mean fitness as natural selection brings the population to the stable gene frequency equilibrium, at which mean fitness will also be at a local maximum. Analogous processes can occur with other genetic processes, such as recombination. Again, in some of these cases, mean fitness does not continue to decline.

But there are also cases where fitness may continue to fall, and natural selection never produces a recovery in mean fitness. *Meiotic drive* is a well-known example of this. Meiotic drive occurs when some genes pervert segregation rates in their favor, so that, despite being deleterious, they spread through

populations. Another situation in which mean fitness can fall is brought about by natural selection itself. The fitness of a mating with males and females can be a nonlinear function of the genotypes of the two organisms mating. If such nonlinearities are sufficiently severe, natural selection on fertility can actually drive fitness to lower and lower levels, at least in theory. No prominent empirical examples of this process are known, however, at this time.

The point that these examples serve to make is that, while it is conventional in evolutionary biology to expect improved adaptation from the action of natural selection, there is no absolute warrant, either in theory or in fact, for this assumption. Theory and experiment both indicate that a process of adaptation is usually brought about by natural selection. But it is not always brought about by natural selection.

When natural selection does act, however, to establish a process of adaptation, what can we say about that process? This is one of the three major research projects of evolutionary biology (the other two being the inference of phylogeny and the study of the genetic material used by evolution). Thus our understanding of adaptation as a process is undergoing continual upgrading as our understanding of natural selection improves.

At the most basic level, however, there are some essential features of adaptation by natural selection that can be taken as well-established. There is no general or consistent pattern to natural selection. Specific populations may undergo very intense selection for a short period of time. One of the best studied examples of this is the recent work on the evolution of Darwin's finches on the Galapagos, particularly the effects of drought on bill size (Grant, 1986). However, for most populations, it is usually very difficult to detect the action of natural selection. It is either too weak or too variable in direction (Abrahamson and Weis, 1997). Some of the cases where natural selection can be readily detected as working in each generation to produce adaptation involve human disturbances, ecological events that are unlikely to reflect the evolutionary situation of populations that have been spared artificial disruption. The classic example of this scenario is the evolution of wing camouflage in the moths of industrial Europe, in which natural selection was generated because soot blackened the tree trunks on which these moths rested, making the light-colored moths stand out against a black background. The very artificiality of this case, however, underscores the point that we do not normally find such cases of unequivocal selection when we study natural populations.

This leads to the next major point about adaptation as a process: it is hard to detect. Therefore, adaptation as a process tends to be assumed by evolutionary biologists more than it is actually demonstrated. And the teasing out of the mechanistic particulars of adaptation as a process is almost never accomplished. This central problem has led to a pervasive weakness in the scientific analysis of adaptation as a process, with unfortunate consequences that will be reviewed below.

Adaptation as a Product of Evolution

The view of adaptation as a product of evolution does not logically require that it be a product of natural selection.

An adaptation can arise evolutionarily from selection on some other character(s), or it might arise from some nonselective process, such as inbreeding or genetic drift. Thus, for example, a spider's web might have evolved because of selection for prey capture, yet it may also constitute an adaptation that enables spiders to obtain water from dew condensing on the web. This raises the question, if adaptation is divorced from the process by which it arose, then how is it to be distinguished from the other characteristics of an organism?

The conventional solution to this problem is to define adaptations as those products of evolution, however generated, that enhance the fitness of the organism. Nominally, this requires that fitness be measured with and without the character(s) that are presumed adaptations. This is a difficult enterprise for two reasons.

First, it is often difficult to perform the surgery, or other manipulation, required to make organisms without the adaptation in question. However, it is in precisely this area where significant progress has been made in studies of adaptation (e.g., Sinervo and Basolo, in *Rose and Lauder, 1996*). Evolutionary biologists are now successfully ablating tissues and grafting on additional body parts, in order to test the fitness consequences of the possession or loss of particular structures that are being evaluated for their status as adaptations. Manipulation of clutch size by removal or addition of eggs has been a traditional method in studies of vertebrate life-history adaptations. Research in this area now manipulates fertility and egg size by a variety of techniques, including microsurgery. The resources of modern molecular biology are likely to give evolutionary research even more power to manipulate phenotypes.

Second, the measurement of fitness is difficult in most organisms. In organisms that reproduce strictly by dividing in two, without sex, fitness can be measured fairly easily from estimates of viability between bouts of fission. In every other kind of organism, sex and variable numbers of offspring make the estimation of fitness extremely difficult. Perhaps the most difficult character of all for the estimation of fitness is male mating success. This difficulty arises because the attribution of maternity is usually fairly secure, while the attribution of paternity is often pure speculation. This is an area where the recent findings of behavioral ecology suggest considerable grounds for pessimism. Pairs of birds, for example, may indeed remain together for life, sharing the tasks of caring for young, foraging for food, and nest construction. But molecular genetic analysis of pedigrees frequently reveals that the "monogamous" female has had sex with another male of the species, while the male has himself dallied. Similar patterns are well-known from human paternity cases. Then there are the species that are either highly promiscuous, such as chimpanzees, or ejaculate gametes externally, such as most fish. In these species, there are no mated pairs to keep track of over the long-term. For all these reasons, estimating the Darwinian fitness of an individual having a particular phenotype is often extremely difficult, if not practically impossible.

The fallback position of many biologists, especially functional morphologists, comparative physiologists, and behavioral ecologists, has been to use a surrogate for fitness. Such surrogates might include mechanical efficiency, conservation of metabolic energy, number of copulations, and so on.

The assumption is usually made that such surrogate measures will always be positively correlated with fitness. When they improve, fitness should increase. Unfortunately, it is likely to be precisely characters of this kind that will show diminishing returns, rather than a stable positive correlation with fitness. Mechanical efficiency is patently not the only impact of structure on fitness. Structures may be costly to develop, or they may impede movement. Evolution is unlikely to maximize each and every "design feature" of an organism, even if there were no genetic constraints preventing the realization of any particular phenotype. Therefore the expedient of using surrogates for fitness is not likely to be reliable in many cases.

If fitness itself cannot be accurately measured, and surrogates for fitness cannot be relied on either, it is difficult to see how the concept of adaptation as a product of evolution can be used in most cases. There are pleas to the effect that some characters are so intuitively beneficial that they cannot be reasonably denied the status of adaptations. Legs must be adaptations for terrestrial locomotion, large brains must be adaptations for life as a tool user, and so on. However, limbs may be used for many functions, not just locomotion. The human brain has also been explained as an adaptation for social behavior, not the use of tools. Supposedly obvious cases turn out to be far from obvious once a diversity of possible scientific interpretations is taken into account.

Evidence for Adaptation

If both basic definitions of adaptation are allowed, then there are two different lines of evidence for the existence of adaptation. The first is simply the action of natural selection. If adaptation is the process of natural selection, then any evidence for such selection is in turn evidence for adaptation. The second line of evidence is supplied whenever there are data showing an increase in fitness when a particular character is acquired. Together, the accumulated evidence bearing on both of these points helps establish the importance of adaptation as a feature and as an outcome of the evolutionary process.

Evidence for Natural Selection

If Darwin generally lacked evidence for natural selection in nature, modern evolutionary biology has supplied an abundance of such evidence (e.g., *Endler, 1986*). There are the classic studies of industrial melanism and there are the recent studies of drought selection in Darwin's finches (*Grant, 1986*). But there are many other examples of natural selection in the wild, dating back to Weldon's study of carapace width in estuarine crabs during the 1890s. Indeed, natural selection is such an obvious feature of the living world that it is now considered in discussions of such practical medical problems as the prescription of antibiotics and the treatment of the human immunodeficiency virus. Thus the general principle that there is a process of adaptation involving natural selection is not in any reasonable doubt.

The evidential problems instead concern the importance of the process in any particular instance. The idea of an adaptive process shaping the course of evolution is very attractive,

because it can be used to support the interpretation of evolutionary change in terms of natural selection. But as discussed already, the demonstration that such a process is occurring is usually very difficult. And the possibility that other evolutionary processes are involved, processes that do not involve adaptation by natural selection for the character of interest, cannot be dismissed out of hand. This renders most casual *post hoc* invocations of natural selection essentially dubious. Whatever the specific features of natural selection, casually invoking it as an explanation for all features of life is no longer reputable behavior in evolutionary biology.

This means that, while there are some specific studies that provide excellent evidence for adaptation by natural selection, in most cases scientists are not in a position to interpret an evolutionary process as being driven by natural selection. It may be allowed as a possibility, but further study is usually required before a particular evolutionary change can be taken as brought about by natural selection, even when such an interpretation seems intuitively natural.

Evidence for Increased Fitness

Even if it is difficult to establish the nature of the evolutionary process, surely the products of evolution are easier to categorize as adaptive? For the reasons listed above, however, it is often difficult to make an accurate determination concerning whether or not the possession of a particular character increases fitness. In particular, it is not enough to show that a particular function, say locomotion, has been improved, perhaps by a longer hind-limb, because such demonstrations do not define the effect on fitness as a whole. A particular function could be improved while fitness itself is reduced.

At present, some of the best demonstrations of adaptation come from the field of behavioral ecology. Of particular value have been manipulative experiments which change the behavior or morphology of study animals and plants. These studies have supplied many instances in which artificially created deviants have demonstrably reduced fitness (Sinervo and Basolo, in *Rose and Lauder, 1996*).

There is a great deal of potential for the study of molecular biology to extend the power of manipulation in the study of adaptation, particularly with genetic transformation and the insertion of genes with artificially inducible expression. Some of these studies have measured the effects on adult survival of gene insertions (*Fleming and Rose, 1996*). Fitness could also be measured in such experiments.

An alternative approach is to measure the relationship between the variation of a character and fitness in polymorphic populations. Much of modern evolutionary quantitative genetics collects data of this kind. One of the central concerns in these studies is the delimitation of optima for fitness as a function of quantitative characters.

Finally, natural selection can be imposed on populations in the laboratory, which results in perturbed values for selectable characters. If the selection is then relaxed, and the original character-state was adaptive, then the character should be driven back to its original state. This result has been observed in several studies (e.g., *Service et al., 1988*; *Teotonio and Rose, 2000* and *Passananti et al., 2004*). Such patterns of

reversion are expected to occur especially when there are trade-offs between functional characters, such that high values of one character are associated with low values of other characters. Interestingly, these kinds of phenotypic reversions are not always accompanied by complete genotypic reversions (*Teotonio et al., 2009*).

The Genomics of Adaptation

Genomics, a discipline still in its adolescence, has revolutionized the study of adaptation over the past decade. The tools of genomics, including genome-wide surveys of gene expression and allele frequencies, have developed into powerful means of describing differences, at the molecular level, between individuals with or without an inferred adaptive character. While these tools are sometimes used to describe natural populations, such as those situated along latitudinal gradients (e.g., *Turner et al., 2008*), they are perhaps more useful when applied to populations evolved in the laboratory. Genomic comparisons of experimentally evolved populations to ancestral controls have usually employ microbial models with small genomes, such as bacteria (i.e., *Barrick et al., 2009*) or yeast (i.e., *Dunham et al., 2002*).

Recent work by *Burke et al. (2010)* offered the first genome-wide survey of allele frequencies in experimentally evolved *Drosophila* populations; in other words, they associated particular allelic variants with characters that underwent dramatic and reproducible change as a result of laboratory selection. The study used populations of fruit flies that had been selected for very rapid development for over 600 generations, which resulted in individuals with enhanced early-life fitness components, compared to individuals from control populations. Burke and colleagues identified many genomic regions that show strong allele-frequency differentiation in response to selection, and these regions included over 500 individual genes. But perhaps the real result of interest is that Burke and colleagues found no evidence for the complete fixation of any of the thousands of nucleotide polymorphisms that strongly responded to selection. In asexually reproducing systems, adaptation is thought to be driven by the sequential fixation of newly arising, beneficial mutations (e.g., *Barrick et al., 2009*). *Burke et al. (2010)* failed to observe evidence of this phenomenon. Instead they found widespread heterozygosity across the genome, even at loci highly differentiated in terms of allele frequency. This raises important questions about the nature of adaptation, especially whether it operates by the same mechanisms in asexual versus sexual organisms. These questions will undoubtedly be addressed in the years to come, as the technology for exploring whole genomes becomes ever more informative and cost-effective.

Critique of Adaptationism

Adaptationism

The record of classical thinking, such as that of Aristotle, illustrates the extent to which the human mind is attracted to the idea of beneficent organization in the natural world. Many

classical scholars believed this even when they had no particular scientific theories to buttress the concept.

Darwinian evolution is thus an almost irresistible temptation for those who wish to infer function in the living world. Darwinism guarantees a role for natural selection in evolution, and it guarantees the existence of adaptation among the characters of organisms. But it does not guarantee that selection and adaptation must be everywhere prepotent, at all times, and in all respects.

Nonetheless, there is a variant form of Darwinism that flourished particularly in the 1950s and 1960s, a variant that assumed that all of the attributes of an organism are shaped by natural selection to the end of increased fitness. On this version of Darwinism, now called “adaptationism,” all characters are adaptations and all nontrivial evolutionary processes are driven by natural selection. In effect, this school of thought made the study of evolution tantamount to the study of adaptation.

Among the effects of adaptationism on scientific practice was the notion that there must always be an adaptive explanation for each and every organ, structure, or behavior. Therefore, if an adaptive explanation for a particular structure has not been found, greater efforts must be made to discover its adaptive value. Alternative evolutionary processes (genetic drift, inbreeding, meiotic drive, etc.) must not be considered until all possible adaptive explanations have been tried and found wanting.

During its heyday, adaptationism put adaptation at the center of evolutionary biology, and to some extent at the center of all of biology. The many theoretical and experimental problems facing the study of adaptation were minimized or dismissed altogether.

The Rejection of Adaptationism

From the late 1960s until the early 1980s, adaptationism suffered a series of blows from which it has yet to recover. The first of these was the detection of a vast amount of molecular genetic variation, first by protein electrophoresis and later by DNA sequencing. The significance of this finding for adaptationism is that most species appear to have far more segregating genetic variation than is likely to be explicable in terms of natural selection. Therefore, natural selection probably isn’t prepotent at the molecular level. The scientific consensus now is that many of the alleles that arise and eventually become fixed during evolution are merely neutral variants of already extant alleles. A great deal of genetic evolution has occurred, but much of it has not been driven by natural selection.

A second event was the publication of *Adaptation and Natural Selection* by Williams (1966). One of the common evasions of the adaptationists was to invoke group selection when they couldn’t explain a particular character in terms of individual selection. Thus many of the social behaviors of colonially nesting birds were explained in terms of adaptations for group selection. Williams pointed out that many of these explanations were highly dubious. He argued that the inference or explanation of adaptations required greater restraint, particularly where social behavior was concerned. This undercut group selection, one of the ways in which adaptationists had been able to discover adaptations

underlying seemingly maladaptive behavior, such as biological altruism. In so doing Williams also helped expose the extent to which adaptationism was based more on dogma than well-founded science.

The third, and culminating, event in the decline of adaptationism was the publication of the “Spandrels of San Marco” paper by Gould and Lewontin (1979). In this paper, Gould and Lewontin hold up for ridicule the adaptationist assumption that there has been a history of selection directly for each and every significant attribute of an organism. They follow Voltaire in his satirizing of such intellectual figures as Spinoza, particularly their boundless belief that “this is the best of all possible worlds,” except that Gould and Lewontin satirize the adaptationist assumption of an all-powerful beneficent natural selection.

These events essentially undermined adaptationism as a dominant movement within evolutionary biology. Adaptationists remain scattered through biology, including such fields as molecular biology, comparative physiology, and systematics. But the powerful hold that they had on evolutionary biology in the 1950s was broken.

Adaptation after Adaptationism

Though adaptationism was clearly in error about the universality of adaptation in the living world, its demolition brought with it something of an overreaction. Many evolutionary biologists effectively rejected the concept of adaptation as a whole. They refused to work on the problem and they criticized those who did. Since 1980, the study of phylogeny has become the central concern of evolutionary biology. The study of adaptation, for some, is now a marginal, somewhat disgraceful, practice within biology as a whole.

Replacing the study of adaptation was the study of “constraints.” Constraints in evolutionary biology are factors that prevent the achievement of an optimal adaptive outcome. Constraints have been discovered promiscuously in the evolutionary machinery: lack of genetic variation, linkage disequilibrium, too much environmental variation, too little environmental variation, epistasis, temporally variable selection, spatially variable selection, and so on. Evolutionary biology went from a doctrine where adaptation was everywhere to a doctrine where adaptation had disappeared, to be replaced by paralyzing constraints.

In the 1990s, there was some stabilization of views on the topic of adaptation. Less of a pariah among evolutionary topics, an edited volume entitled “Adaptation” was published in 1996. Evolutionary biologists were spending more time using experimental and other techniques that could test for adaptation, rather than simply assuming its presence or absence.

The comparative study of adaptation was greatly improved by an infusion of phylogenetic techniques. For example, if it was hypothesized that the gill structure of a fish species was an adaptation to a new way of life in salt water, but two species that had evolved in fresh water exclusively also have that gill structure, then the phylogenetic information indicates immediately that the basic adaptive hypothesis is not correct.

Laboratory selection is used more often now to study adaptation, with greater replication and greater attention to

designs that can be used to make inferences about selection. The great advantage of performing selection in laboratories is that selective process can be studied with greater statistical power and control, compared to the “experiments” of nature, all of which are unique and uncontrolled. For example, instead of studying the water physiology of two desert insect species compared to two forest insect species, evolutionary biologists instead select insects under conditions of desiccation, using replicated selection lines and controls maintained free of desiccation (Bradley *et al.*, 1999). Instead of dealing with possible historical accidents that might have differentiated species in the wild, selected laboratory populations provide good material for critically testing theories of adaptation to particular environmental conditions.

Another major development in the study of adaptation has been the use of natural populations, especially manipulated natural populations, in studies that approximate laboratory experiments. Reznick (Reznick and Travis, in Rose and Lauder, 1996) has studied guppy evolution in the streams of Trinidad. Multiple streams pass in parallel through highly uniform drainage systems, giving the streams isolated guppy populations, but populations that evolve under effectively identical conditions. This experimental system has provided tremendous opportunities for the study of adaptation in the wild, with both replication and controls.

The study of adaptation now proceeds with much more skepticism than in the past. At the same time, empirical methods for studying it have been greatly improved. The prospects have never been brighter for a genuine scientific analysis of adaptation, as opposed to the blithe speculations of the past.

Glossary

Adaptive shift A change in the nature of a trait (morphology, ecology, or behavior) that enhances survival and/or reproduction in an ecological environment different from that originally occupied.

Allopatric speciation The process of genetic divergence between geographically separated populations leading to distinct species.

Character displacement Divergence in a morphological character between two species when their distributions coincide in the same ecological environment compared to overlap of the character in question in the two species when they are geographically separated.

Convergence The evolution of similar characters in genetically unrelated or distantly related species, often as the result of selection in response to similar environmental pressures.

Ecological release Expansion of habitat, or ecological environment, often resulting from release of species from competition.

Founder effect Random genetic sampling in which only a few “founders” derived from a large population initiate a

new population. Since these founders carry only a small fraction of the parental population’s genetic variability, radically different gene frequencies can become established in the new colony.

Key innovation A trait that increases the efficiency with which a resource is used and can thus allow entry into a new ecological zone.

Natural selection The differential survival and/or reproduction of classes of entities that differ in one or more hereditary characteristics.

Sexual selection Selection that acts directly on mating success through direct competition between members of one sex for mates or through choices made between the two sexes or through a combination of both modes.

Sympatric speciation The process of genetic divergence between populations occupying the same geographic range leading to distinct species.

Taxon cycle The repetitive pattern by which widespread dispersive stage I populations or species give rise to more restricted and specialized stage II populations or species; subsequent divergence leads to stage III local endemics.

History of the Concept

Beginning with the work of **Darwin (1859)** on the Galapagos fauna, the concept of adaptive radiation, in terms of diversification of ecological roles by means of natural selection, has been recognized. The term was first used by **Osborn (1902)** in describing parallel adaptations and convergence of species groups on different landmasses. Subsequently, it was developed as a major tenet for arguments presented in the modern synthesis by **Huxley (1942)**. **Simpson (1953)**, working on paleontological data, discussed the importance of key innovations in triggering adaptive radiation. For a detailed history of the concept of adaptive radiation, see **Givnish (1997)**. Much recent information has been added, particularly during the past decade with the rise of molecular methods (**Givnish and Sytsma, 1997**).

Nonadaptive Radiations

The term “nonadaptive radiation” has been used to describe situations in which species proliferation has not been attended by diversification of ecological roles (**Gittenberger, 1991**). When proliferation is simply a consequence of isolation, with

isolated sibling species maintaining similar ecological affinities, then the radiation cannot be considered “adaptive.” As will be described later, isolation has been invoked to explain the initial divergence of taxa in some radiations (e.g., Galapagos finches and cichlid fish), with the adaptive phase not occurring until recently diverged sibling species become sympatric. However, there are some cases of nonadaptive radiation, with many allopatric and ecologically similar species. Most of these radiations are caused by changes in topography that, instead of opening up new habitats, have served simply to isolate a previously more widespread species. For example, isolated mountaintops and other continental refugia have allowed species long periods of evolution in isolation, without any ecological change. This may lead to patterns of considerable genetic distance between morphologically similar species from different isolates (**Schneider and Moritz, 1999**). Similarly, diversification of snails on islands has frequently been attributed to topographical isolation (e.g., Crete (**Gittenberger 1991**) and Madeira (**Cameron et al., 1996**)). In general, it appears that (i) nonadaptive radiation occurs if there is isolation without any novel ecological opportunity and (ii) coexistence of species within a lineage will not occur in nonadaptive radiations but is a primary characteristic of adaptive radiations.

Factors Underlying Adaptive Radiation

The common requirement for triggering adaptive radiation is the opening up of ecological space. This may be allowed by intrinsic factors, i.e., something that changes in the organism to allow radiation to occur; for example, evolution of tolerance toward noxious plant chemicals (Farrell and Mitter, 1994; Mitter *et al.*, 1988). Alternatively, it may occur as a result of extrinsic factors; for example, it has been reported to occur in geological history after an influx of nutrients into the system (Vermeij, 1995), in recent evolutionary time when new islands are colonized (Wagner and Funk, 1995; Liebherr and Polhemus, 1997), and in ecological time when a new habitat opens (Rainey and Travisano, 1998).

For ancient radiations, it is often difficult to determine the relative importance of intrinsic and extrinsic factors in allowing adaptive radiation. Factors associated with such radiations include (i) coincidence (after a slight delay) with major extinction episodes (Sloan *et al.*, 1986) and (ii) radiation of a group frequently starting from a small, unimpressive set of species from an earlier period. For example, fossil ammonites (shelled cephalopod mollusks) reveal episodes of tremendous proliferation and extinction through the Devonian, Triassic, Jurassic, and Cretaceous (Figure 1; Lehmann, 1981). Echinoderms show a similar pattern, originating in the Ordovician and undergoing small radiations until all but one lineage went extinct by the end of the Permian (Smith, 1984). These then radiated extensively in the Triassic–early Jurassic, and the current diversity of forms remains similar to what arose at that time.

The great placental radiation (>4300 species) has been attributed partly to the extinction of many reptilian groups at the end of the Cretaceous (Simpson, 1953). The parallel adaptive radiation of marsupials in Gondwana has also been

attributed to the Cretaceous extinctions and subsequent opening of ecological space (Springer *et al.*, 1997). However, within each lineage (placentals and marsupials) key innovations may have been involved: The radiation of ungulates and ruminants is associated with the opening up of the savannas (Figure 2) but would not have happened if the organisms did not develop the morphological and physiological features necessary to exploit the habitat. Similarly, the radiation of the diprotodontians appears to have commenced in the Eocene and may have been promoted by a key adaptation for herbivory (Springer *et al.*, 1997). The actual basis for radiations subsequent to extinction episodes is still a subject of debate, particularly because coincidence between extinction events and subsequent radiations is generally poor. Vermeij (1995) argued that there is a stronger coincidence of species diversification episodes with increases in nutrient input into the biosphere.

We consider factors underlying species proliferation under two headings: intrinsic factors, and the concept of “key innovations,” and extrinsic factors, including environmental change and colonization of isolated landmasses.

Intrinsic Factors: Key Innovations

Simpson (1953) suggested that the evolution of a suite of traits, or key innovations, that increase the efficiency with which a resource is used might allow species to enter a “new” adaptive zone, and the ecological opportunity thus allowed might promote diversification. The concept of the key innovation is an essential element in hypotheses of the evolution of specialization and subsequent adaptive radiation in herbivorous insects. However, the nature of key innovations is not often clear. In an attempt to define more clearly the concept, Berenbaum *et al.* (1996) examined cytochrome P450S and its

Figure 1 The differentiation of the ammonoids from the Devonian to the Cretaceous, based on the number of genera. Striped area, new genera; Hatched area, continuous genera.

Figure 2 Plot of herbivore primary consumer diversity, taxonomic composition, and inferred dominant habitat type in North America for successive land-mammal ages during the Cenozoic. Vertical dashed lines indicate boundaries. Reprinted from MacFadden, 1992. Fossil horses: systematics, paleobiology, and evolution of the family Equidae.

relation to the adaptive radiation of butterflies. They found high levels of diversification in substrate recognition sites between species that do not share the same set of host plants; the reverse was true for those species that do share host plants. This result was taken to indicate that specialization may necessitate conservation of this region of the genome and could therefore be considered a key innovation.

Many attributes of species have been proposed as key innovations, or characteristics that have allowed diversification and proliferation. They generally involve the development of features that modify biotic interactions. Particular examples include the development of toxicity in plants (that allows them to “escape” predatory pressure of insects) and subsequent development of tolerance to the toxin in insects which allows them to radiate onto the plants. Symbioses are another possible “evolutionary innovation,” allowing the abrupt appearance of evolutionary novelty (Margulis and Fester, 1991). They provide a possible avenue through which taxonomic partners can enter into a new set of habitats unavailable to one or both of the symbiotic partners alone. One of the most famous examples is the radiation of ruminants in the African savannas, which has been attributed partially to the development of gut endosymbionts and the concomitant ability to digest cellulose. Among the Foraminifera, Norris (1996) showed that photosymbiosis appeared in the fossil record in synchrony with the taxonomic differentiation of three of the dominant surface water foraminifera groups in the Paleocene and early Eocene. This radiation was not paralleled in the asymbiotic sister group. Symbiosis was suggested to provide a jump-start for diversification by providing the ecological opportunity.

In their classic paper, Ehrlich and Raven (1964) examined how interacting species in themselves may create ecological opportunity, and hence periodically enhance evolutionary rates, through a broad “coevolutionary” response. They hypothesized that, when plant lineages are temporarily freed

from herbivore pressure via the origin of novel defenses, they enter a new adaptive zone in which they can undergo evolutionary radiation. However, if a mutation arose in a group of insects that allowed it to feed on one of these previously protected lineages of plants, it would also be free to diversify in the absence of competition. Ehrlich and Raven envisioned this as a step-like process in which the major radiations of herbivorous insects and plants have arisen as a consequence of repeated opening of novel adaptive zones that each has presented to the other over evolutionary history. This idea, termed the “escalation/diversification” hypothesis (Berenbaum and Feeny, 1981), has been supported by the work of Farrell and colleagues, who have studied insect diversification in the context of host plants (Figure 3). Repeated evolution of angiosperm feeding in phytophagous beetles is associated with an increased rate of diversification (Farrell, 1998). Similarly, there is consistently greater diversity among plants in which latex or resin canals have evolved as protection against insect attack (Farrell et al., 1991).

Since Ehrlich and Raven, there has been a tremendous amount of research on the role of coevolution in dictating patterns of diversification. One of the major avenues that this research has taken is the study of the extent to which the phylogenetic order of divergence among herbivores or parasites corresponds to that among their hosts as a result of “parallel diversification” (Farrell and Mitter, 1994). A strongly corresponding evolutionary history might suggest a coevolutionary response between the host and the herbivore or parasite. However, there appear to be few cases, at least among insect–plant interactions, in which the phylogeny agreement is precise. In most cases there has been periodic transfer of species to more distantly related hosts.

How do the coevolution arguments invoke adaptive radiation? The situation that Ehrlich and Raven (1964) envisioned was one in which the host radiated prior to exploitation and subsequent radiation by the herbivore (“escape and radiation”).

Figure 3 Phylogeny estimate of *Tetraopes* beetles based on morphology and allozymes, compared to literature based relationships of host plants. Host *Asclepias* shows an apparent progression toward increased complexity and toxicity of cardenolides, perhaps representing escape and radiation. Reproduced from Figure 6 in Farrell BD and Mitter C (1994) Adaptive radiation in insects and plants: Time and opportunity. *Am. Zool* 34: 57–69.

This might be considered analogous to the opening up of an array of ecological opportunities every time the innovation arose for either “escape” or “exploitation.” The established diversity of hosts could provide the necessary diversity of ecological roles and associated adaptations. Where coevolution involves parallel diversification, adaptive radiation may not be involved. In particular, parallel diversification might be considered analogous to geographic separation, with divergence of the host causing isolation of the herbivore. This might then be considered a nonadaptive radiation. On the other hand, parallel diversification might cause an escalation in responses, with enhanced toxicity and reciprocal tolerance evolving in step-like progression (Berenbaum, 1983; Farrell and Mitter, 1994). In this latter scenario, adaptive radiation can be implicated for both the herbivore and the host.

Extrinsic Factors

Speciation rates are generally considerably higher in novel environments, whether a lake in the middle of a continent or an island in the middle of the ocean (Schluter, 1998; Figure 4).

Environmental Change

Environmental change has frequently been implicated in species radiations, with the opening up of new habitat. Diversification has frequently been suggested to occur under stressful conditions [e.g., for the origin of angiosperms

(Shields, 1993) and the recent diversification of mole rats (Nevo *et al.*, 1984)]. However, any novel environment in which the organism is subjected to a new selective regime could be considered “stressful.” In other words, an organism that successfully invades a novel environment will inevitably be subject to stressful conditions. However, no matter whether the novel environment is considered stressful or simply a situation in which the organism is subject to a novel set of selective forces, it does appear to be associated with acceleration in evolutionary rates (Nevo *et al.*, 1984; Shields, 1993).

The evolution and adaptive radiation of the African cichlids (Figure 5) appear to have been initiated by environmental change. Geological activity 20 million years ago (mya) caused the rivers in the area to become progressively meandric and swampy while still connected to the Zaire hydrological system. Over time, a mosaic of small, shallow, and isolated lakes developed, and finally the drainage system became closed and the lakes deepened (approximately 5 mya). The diversification of cichlid fish appears to have been initiated when river species moved into the swamp (Sturmbauer, 1998), and then successive radiations were associated with the development of protolakes and subsequently deep lakes.

In geological history, environmental changes appear to form the basis of the Phanerozoic revolutions (Vermeij, 1995): Increasing temperature and nutrient supplies as a result of submarine vulcanism may have triggered later Mesozoic and perhaps early Paleozoic diversification episodes. Similar

Figure 4 Per capita speciation rates of clades in novel environments ($\circ$) and in closely related “control” lineages inhabiting other environments ($\bullet$). Rate estimates (y , left axis) are plotted against a dummy variable, the median of y -values. The solid line indicates $y = x$; points above the line therefore exhibit high rates. Rates were calculated from phylogenies based on allozyme frequencies. Time is measured in units of genetic distance (D). The calculation of rate y assumes exponential growth of species number: $y = \ln(N)/t$, where N is the number of extant species in a clade and t is its estimated time of origin. Corresponding times required for species number to double are indicated on the right; the number of species in a clade doubles after $\ln(2)/y$ time units. Reproduced from *Endless Forms: Species and Speciation*, ed. by D. J. Howard and S. H. Barlocher, © 1998 by Oxford University Press, Inc.

factors may underlie the iterative radiations of ammonoids throughout the geological record (Dommergues *et al.*, 1996). Each radiation appears to have originated from a few taxa, which went on to produce a wealth of morphological diversity. Although well documented for ammonoids, the pattern of iterative radiation is extremely rare in the fossil record. Within the total morphospace defined for the first three Jurassic stages, the radiation corresponds to a string of “events” separated by episodes of morphospace collapse. During each event, only a portion of morphospace (<45%) was filled; some morphs were reiterated, but each event had its own particular derived morphs.

Colonization of Isolated Landmasses (Particularly Oceanic Islands)

Isolated landmasses that have never been in contact with a source provide abundant opportunity in terms of newly available “niche space” for those taxa that manage to colonize them. Isolated archipelagos are generally considered in a different category of adaptive radiations, although they are really just special cases of environmental change: the appearance of a new environment, which happens to be isolated in the ocean. This has much in common with the formation of, for example, a lake in the middle of a continent. In either case, newly created habitats that are isolated from a source of colonists provide an extraordinary opportunity for adaptive radiation. Both the novelty and the isolation are key features in allowing adaptive radiation in such areas. If a new habitat appears in close proximity

Figure 5 Adaptive radiation of cichlid fish, showing convergence in body shapes in Malawi and Tanganyika species. From TREE review. Reproduced from Meyer A (1993) Phylogenetic relationships and evolutionary processes in East African cichlid fishes. *Trends in Ecology & Evolution* 8: 279–284.

to other such habitats, it will be colonized by taxa from those habitats. Species diversity patterns will then match closely the predictions of the MacArthur–Wilson model of island biogeography (MacArthur and Wilson, 1967); that is, species diversity patterns will be governed by ecological processes. As isolation from the source of colonists increases, fewer taxa will be able to colonize the new habitat, and the low rate of colonization may provide sufficient time for species diversification to occur. Adaptive radiations are most likely to occur at the extreme ends of the dispersal range of a given taxon (Whittaker, 1998).

Are Certain Taxa more Likely to Undergo Adaptive Radiation than Others?

Are species predisposed to undergo adaptive radiation because of a broad environmental tolerance, generalized feeding

patterns, or perhaps some proclivity to develop novel associations? This question has been developed by some authors. For example, [Adler and Dudley \(1994\)](#) compared patterns of adaptive radiation among birds and butterflies in the insular Pacific: Birds have undergone extensive adaptive radiation, whereas butterflies have not. They argued that speciation in butterflies may be constrained by the mechanics of insect-plant coevolution that prevents rapid diversification. However, this argument is not well supported because other insects with similar coevolutionary ties have undergone some of the most spectacular insular adaptive radiations known. It appears that almost any group of organisms is capable of undergoing adaptive radiation upon being provided ecological opportunity that it can exploit.

How does Adaptive Radiation get Started?

Initiation of Adaptive Radiation: Genetic Changes

Founder Events

The establishment of species in new environments inevitably involves sampling from the parent population. The size of the sample that can build a new population can be very small (cf. founder effects), although it need not necessarily be so. In particular, if, subsequent to colonization, a very small number of individuals were to proliferate rapidly, there would be little subsequent loss in genetic variability ([Nei et al., 1975](#)). Consequently, the deleterious effects of inbreeding are largely mitigated. However, because the genes represented in the founding population are only a small sample of the original population, genetic drift may be pronounced.

The nature of genetic changes during shifts in population size, particularly those experienced during or after population bottlenecks, has been the subject of considerable controversy in recent years. Clearly, a crash in population size as a result of a genetic bottleneck or founder event will cause allele frequencies at some loci to differ from those of the parent population because of accidents of sampling ([Templeton, 1980](#)). The debate concerns the nature of genetic changes that occur subsequent to the bottleneck, during the period of population growth. Traditional arguments suggested that founder events may trigger rapid species formation ([Carson and Templeton, 1984](#)). However, recent arguments have largely refuted the contribution of founder events to reproductive isolation ([Barton, 1996](#)).

Other possible changes during founder events are due to genetic reorganization. [Carson \(1990\)](#) proposed that blocks of loci are destabilized when a newly founded colony undergoes a flush of exponential growth, during which time selection is relaxed and recombinants that ordinarily have low fitness survive. Release of additive genetic variance through change in epistatic interaction may allow formation of novel recombinants ([Goodnight, 1988](#)). Recent work has questioned the importance of epistatic interactions and the nature of “destabilization” among blocks of loci during periods of reduced population size. [Slatkin \(1996\)](#) discussed changes that might occur subsequent to reduction in population size in terms of conventional population genetics. Genetic drift will be the primary force causing genetic changes during the

bottleneck. However, when the population starts to grow, the influence of genetic drift is expected to become weaker so that selection is most effective during and immediately after the period of rapid demographic expansion. On the other hand, [Otto and Whitlock \(1997\)](#) argued that, although it is true that the probability of fixation of beneficial alleles present during the bottleneck is increased during the subsequent period of population growth, a large proportion of alleles are lost during the bottleneck and few new mutations can occur while the population is at small size. The resultant effect of these opposing forces is that the number of beneficial mutations fixed per generation remains virtually unchanged by the bottleneck. Nevertheless, selection subsequent to a genetic bottleneck has an important effect on alleles that are initially rare and that would tend to be lost to stochastic events in populations of constant size ([Slatkin, 1996](#)). In addition, there is evidence that stress on a genetic system (e.g., as a result of a population crash) may activate transposable elements ([Carson, 1990](#)), which can exercise a mutagenic effect by interrupting structural or regulatory regions of the genes into which they become integrated. Therefore, mutation rates may actually be higher in founder populations, providing raw material on which selection can act, and which in turn could lead to a rapid recovery of genetic variability. There are thus two processes which can be associated with colonization events: (i) possible genetic changes/restructuring within the population and an expected loss of genetic variability and (ii) the subsequent recapturing of genetic variation during population expansion as a result of selection ([Slatkin, 1996](#)).

Rapid Proliferation and Hybridization

Differential mixing of characters during segregation of populations and species may occur as a result of hybridization of newly divergent taxa ([Harrison, 1993](#)). Behavioral changes during founder events may facilitate hybridization because it has been suggested that sexual interactions may lose specificity subsequent to a founder event ([Kaneshiro, 1989](#)). Closely related heterospecifics may therefore hybridize and/or introgress subsequent to colonizing a new landmass, but the extent of genetic exchange may differ between regions of the genome ([DeSalle and Giddings, 1986](#)). Differences may be particularly pronounced between character sets involving nuclear and extranuclear DNA, such as mitochondrial or chloroplast DNA. Extranuclear DNA differs from nuclear DNA because of its greater sensitivity to the effects of each founder event due to its smaller effective population size (one-fourth) relative to nuclear DNA, attributable to its transmission primarily through the female line, and its existence as a single copy ([Avise, 1991](#)). Analysis of extranuclear DNA information will result in a gene genealogy, but it is likely to provide an incomplete history of the organisms if much hybridization has taken place. The occurrence of hybridization may explain differences that have been found between nuclear and mitochondrial phylogenies, particularly for the Hawaiian *Drosophila* ([DeSalle et al., 1997](#)). Indeed, natural hybridization with the formation of fertile hybrids has been documented between closely related species of *Drosophila* on the youngest island of the Hawaiian Islands ([Carson, 1989](#)). Among silverswords, hybridization has been

implicated as an important element in the adaptive radiation of the group (Baldwin, 1997).

Among the Galapagos finches, recent molecular data have failed to distinguish species limits, at least for the morphologically defined ground and tree finch species: Individuals representing different morphologically identified species are intermingled. This may be explained by interspecific hybridization and/or sorting of haplotypes (Freeland and Boag, 1999). In the case of ground and tree finches, both explanations may apply. The incomplete species differentiation within these taxa may be taken as an indication that adaptive radiation is currently ongoing.

Failure of molecular data to distinguish species limits has been found in several other adaptive radiations. For the cichlid fish of Lake Malawi, it has been suggested that speciation is occurring faster than alleles can become fixed within a species (Moran and Kornfield, 1993). Among Hawaiian crickets, Shaw (1996) comments on a discrepancy between phylogenies generated on the basis of song (Otte, 1994) with that generated from mtDNA variation. Although the discrepancy could be explained by problems with current taxonomic boundaries, and problems with mtDNA lineage sorting, she argues that hybridization and introgression appear to be the most likely explanation.

Although the number of species in which hybridization has been documented is currently small, it is likely to increase as researchers accumulate phylogeographic knowledge based on multilocus molecular data for different radiations.

Initiation of Adaptive Radiation: Ecological Changes

Populations frequently initiate a cycle of change in abundance and distribution upon colonization of a novel habitat or an unoccupied set of niches, during which they undergo ecological release, expand their range, and adopt a more generalized habit (Cox and Ricklefs, 1977). After their initial rise to dominance as widespread generalists, these taxa may subsequently be competitively displaced from much of their original range by younger relatives (Darlington, 1957). Wilson's (1961) "taxon cycle" was used to describe such changes in the distributional pattern of Melanesian ants. He suggested that widespread, dispersive populations give rise to many more restricted and specialized species. Regular changes in ecological and geographical distribution have been recognized in many island systems (Cox and Ricklefs, 1977).

Ecological release may be the precursor to adaptive radiation. This argument has been supported by recent experimental evidence: Rainey and Travisano (1998) studied adaptive radiation experimentally using the bacterium *Pseudomonas fluorescens*. This interesting bacterium is known to evolve rapidly in novel environments, with evolutionary differences detectable in the morphology and ecological affinity of the phenotype. An isogenic population of one morph was propagated in (i) a spatially heterogeneous environment and (ii) a spatially homogeneous environment. In the spatially heterogeneous environment, extensive morphological diversification was found to occur within 3–10 days, resulting in three dominant morphs. This was taken as evidence for diversifying selection. In the spatially homogeneous environment, no morphological variation was found.

The Processes of Adaptive Radiation: Case Studies

What are the factors underlying diversification in an adaptive radiation? This question has fascinated biologists for many years. However, until recently, the characters involved in the adaptive radiation necessarily had to be used as the basis for phylogenetic inference. Given that adaptive radiations are characterized by tremendous levels of convergence in almost every morphological and ecological character, it has been very difficult to interpret evolutionary processes. As Givnish (1997) notes, "any rigorous, noncircular study of adaptive radiation must be based on a phylogeny that has been derived independently of the traits involved in that radiation." Recent advances in molecular techniques, although not without problems of their own, provide an opportunity to obtain such an independent assessment of evolutionary history (see review of arthropod radiations in Hawaii in Roderick and Gillespie, 1998). The following sections outline case studies from a range of taxa, most of which have used a combination of morphological and molecular techniques in an attempt to gain some understanding of processes underlying adaptive radiations.

Galapagos Finches

There are currently 14 recognized species of Darwin's finches in six genera, which have evolved from a common ancestor (Figure 6; Lack, 1947; Grant, 1986). Of these, 13 live in the Galapagos Islands. Based on morphological, behavioral, and ecological data, they have been divided into three lineages: First, the ground finches, *Geospiza* (6 species), which are found in more arid areas of the archipelago and feed on seeds on the ground. Three of the species which are considered the most "finch-like" differ primarily in body and beak size and are known as the large (*G. magnirostris*), medium (*G. fortis*), and small (*G. fuliginosa*) ground finches. The 3 other species of ground finches have longer beaks. Two feed on cactus flowers and pulp as well as seeds and are known as the large (*G. conirostris*) and small (*G. scandens*) cactus ground finches. Finally, the sharp-beaked ground finch (*G. difficilis*) supplements its diet with the eggs and blood of other birds and reptile ticks. Second, the tree finches, which are found mostly in trees and shrubs, are divided into 3 genera: *Cactospiza* [the woodpecker finch (*C. pallida*) and the mangrove finch (*C. heliobates*)], *Camarhynchus* [the large tree finch (*C. psittacula*), the medium tree finch (*C. pauper*), and the small tree finch (*C. parvulus*)], and *Platyspiza* (the vegetarian finch, *P. crassirostris*). All except *P. crassirostris* are insect eaters. Finally, the warbler-like finches, which are small with slender beaks, are in 2 genera: The warbler finch (*Certhidea olivacea*) catches insects like a warbler, and the Cocos finch (*Pinaroloxias inornata*) is the only Darwin finch that lives outside the Galápagos Archipelago. It appears to have colonized Cocos Island from the Galapagos.

Darwin's finches share common features of nest architecture, egg pattern, and courtship displays. They differ in song, morphology, and plumage. Based on morphology, allozyme, and DNA sequence data, the warbler finch *C. olivacea* appears to be closest to the ancestral form. However, recent molecular data indicate that the Cocos finch *P. inornata*

Figure 6 Adaptive radiation of Darwin's finches. Reproduced from Grant (1991).

is closest to the tree finches of the Galapagos (Sato *et al.*, 1999; Petren *et al.*, 1999). Also, the vegetarian finch appears to be ancestral to both the tree and ground finches rather than being a member of only the tree finch group.

Grant (1986) proposed a three-step process to speciation to explain the adaptive radiation of the group: (i) The ancestral species arrives in the archipelago; (ii) the species spreads to other islands and as a result of this, there will probably be some selection and hence differentiation in size because the islands are different; and (iii) members of the original and derived populations encounter each other, and as a result of competition for food and selection against intermediates character displacement causes rapid divergence in feeding structures between the species when they come together. Therefore, the radiation appears to be based on (i) the isolation of the archipelago, which provided ecological opportunity; (ii) considerable distances between the different islands, which has led to infrequent interisland exchange; and (iii) different environments on the different islands, which have selected for different feeding niches both within and between islands.

Hawaiian *Drosophila*

The Hawaiian Drosophilidae represent some of the most striking examples of adaptive radiation known for any group anywhere (Kaneshiro, 1988), with 337 species in the genus *Drosophila* (pomace flies), 19 in *Idiomyia* (picture-winged flies), 122 in *Scaptomyza*, and 11 in *Titanochaeta* (Hardy, 1965; Hardy and Kaneshiro, 1981). Based on the premise that founder events are the most important mechanism of speciation in the Hawaiian *Drosophila*, Kaneshiro (1983) proposed models suggesting the importance of sexual selection in driving species proliferation in these insects. The Hawaiian Drosophilidae, particularly the males of the picture-winged species, often have ornately patterned wings as well as unusual modifications of the mouthparts and legs. The extraordinary manifestations of these features in the male picture-winged species are frequently accompanied by elaborate courtship behavior. In classic studies of picture-winged *Drosophila*, Kaneshiro (1983) found evidence for asymmetrical sexual isolation: Females from a geologically older island were found

to be highly discriminating in terms of mate choice and would not mate with a closely related species from a younger island. In contrast, females from species on the younger island readily accepted males from the older island species. Based on these observations, Kaneshiro proposed that courtship requirements are relaxed during the early stages of colonization of a new island; sexual behavior may then become less constrained and simpler, and there may be more intraspecific variability. In such circumstances, there would be strong selection for less discriminating females because of the difficulties in finding mates and reproducing when the population size is small. Intrasexual selection may then operate to cause divergence of the sibling species during isolation because of a shift in the distribution of mating preferences during the founder/flush cycle (Carson, 1986). The result would be a shift in the mating system, which could then be fixed at a new “equilibrium.”

Evolution of the Hawaiian *Drosophila* is commonly treated as an example of sexual selection influencing speciation (Carson, 1986). The nature of this influence is not entirely clear. *Drosophila heteroneura* and its close relative, *D. silvestris*, are partially sympatric in forests on the island of Hawaii, where they occasionally hybridize. The species are distinguished by the much broader head of *D. heteroneura*. Male aggression and male courtship are the major determinants of male mating success. Accordingly, it appears that male head width is subject to sexual selection through mate choice, although this, and perhaps related sexually dimorphic traits, may not be involved in behavioral isolation (Boake *et al.*, 1997).

A recent molecular phylogeny of picture-winged Hawaiian *Drosophila* showed that clades are characterized according to whether they breed on fungi, leaves, fruit, or bark (Kambyzellis and Craddock, 1997). Suites of reproductive characters (in particular, ovarian egg and ovipositor traits) appear to have evolved together (Kambyzellis, 1993), and adaptive shifts to new breeding sites appear to have been important at least in the early diversification of the group and in some recent speciation events (Kambyzellis and Craddock, 1997). The interplay of such ecological shifts with sexual selection in allowing diversification of Hawaiian *Drosophila* remains unresolved.

Hawaiian Honeycreepers

The endemic Hawaiian subfamily Drepanidinae, or Hawaiian honeycreepers, includes 33 historically known species and at least 22 “fossil” species (Figure 7; James and Olson, 1991). The three tribes are (i) the Psittirostrini, Hawaiian finches (23 species), which includes 5 extant species, 4 historically extinct species, and 14 fossil species; (ii) the Hemignathini, Hawaiian creepers and allies (22 species), which includes 13 extant species, 3 species and 2 subspecies historically extinct, and 6 fossils; and (iii) the Drepanidini, Mamo’s, Iiwi’s, Apapane’s, crested honeycreeper and allies (9 species), which includes 4 extant species, 3 species historically extinct, and 2 fossils. Based on the tremendous morphological and ecological differentiation known from historical and recent collections, these birds have been heralded as one of the best known examples of adaptive radiation. However, the high proportion of currently extinct species makes it difficult to develop hypotheses regarding processes underlying the

Figure 7 The inferred pattern of evolution of dietary adaptations as represented by 16 of the Hawaiian honeycreepers. 1. adaptive radiation. Molecular studies based on extant species suggest that differentiation has occurred between islands only (Tarr and Fleischer, 1995). One might speculate that species have proliferated in a manner similar to that proposed for the finches in the Galapagos, as described previously.

African Cichlids

Lacustrine fish represent some of the most spectacular cases of adaptive radiation in vertebrates (McCune, 1997), with the best known being cichlids. Cichlids are spiny-rayed freshwater fishes that reach their most abundant diversity in Africa, particularly in the great east African lakes of Victoria (>400 species), Malawi (300–500 species), and Tanganyika (approximately 200 species) (Figure 5). In each of these lakes the fish exhibit spectacular diversity in trophic morphology, including specialist algal scrapers, planktivores, insectivores, piscivores, paedophages, snail crushers, and fin biters. In addition to their trophic diversity, they exhibit a striking array of color patterns. They also show complex mating behaviors, polyandrous mating systems, and a tendency to breed in leks. Several factors are considered to be involved in the diversification of these fish. One suggests that morphological adaptation is the primary event underlying speciation (Liem, 1973). The basis for this assertion is their trophic apparatus, which is unique in the possession of two sets of jaws—one in the mouth for sucking or scraping and the other in the throat for macerating, crushing, or piercing. These structures can be modified according to the diet of the fish. The second factor

considered to be involved in allowing reproductive isolation and hence diversification of the fish is sexual selection, which allows subsequent morphological differentiation.

Recent molecular work (Meyer, 1993; Meyer *et al.*, 1996) has shown that cichlids in any one lake are far closer to each other than to morphologically similar species in other lakes. Evolution has generated similar ecomorphs in each of the lakes. There has been considerable debate regarding the nature of the mechanism underlying the proliferation of species within a lake, particularly whether it is considered "allopatric," "microallopatric," or "sympatric" (McCune and Lovejoy, 1998). However, perhaps the most broadly accepted mechanism involves repeated isolation. For example, Lake Tanganyika has apparently undergone repeated decreases in water level (as much as 2000 ft). Populations may have been isolated in small pockets of water for long enough to become reproductively isolated. Sexual selection may play a role in allowing reproductive isolation of the fish subsequent to isolation because closely related species differ primarily in color pattern and not in jaw morphology (Albertson *et al.*, 1999). It appears that morphological adaptation played a role

in the early radiation of the group, resulting in distinct clades that differ in jaw morphology; only minor morphological differences are observed within genera (Stauffer *et al.*, 1997). Recent diversification is largely associated with variation in adult male color pattern.

Hawaiian Silverswords

The Hawaiian silversword alliance has been considered "the best example of adaptive radiation in plants" (Raven *et al.*, 1992). It consists of 30 species in three genera (*Wilkesia*, *Dubautia*, and *Argyroxiphium*) but with one common ancestor. Life form diversity includes trees, shrubs, mat plants, monocarpic and polycarpic rosette plants, cushion plants, and vines that occur across a broad environmental spectrum from rain forests to desert-like settings (Carr, 1985). Major ecological shifts have accompanied speciation in each of the major island-endemic lineages (Figure 8; Baldwin, 1997). The estimated minimum rate of diversification in the silversword alliance (0.56 ± 0.17 species per million years) is comparable to, or higher than, rates of several more ancient continental

Figure 8 Phylogeny of the Hawaiian silversword alliance and the American tarweed genera *Madia* and *Raillardiopsis* based on DNA sequences. Losos; Kevin de Queiroz.

groups that have been regarded as examples of adaptive radiation (Baldwin and Sanderson, 1998).

Lizards in the Caribbean

Currently, 139 species of Caribbean lizards are recognized, 80% of which occur in the islands of the Greater Antilles (Cuba, Hispaniola, Jamaica, and Puerto Rico) (Figure 9). Losos (1992) and Losos *et al.* (1998) found that on each of the islands lineages have diversified in such a way as to occupy a range of ecological roles, with as many as 11 species occurring sympatrically. Different species live, for example, on twigs, in the grass, or on tree trunks near the ground. Twig anoles tend to be slender with short legs and tails, whereas the trunk-ground anoles are stocky with long legs and poorly developed toepads. Losos and colleagues recognized six habitat specialists and called these “ecomorphs,” which are recognizable on the basis of morphological measurements. The same set of ecomorphs are found on each island (with a few exceptions): Four occur on all islands (trunk-ground, trunk-crown, crown-giant, and twig), one occurs on all islands except Jamaica (grass-bush), and one occurs only on Cuba and Hispaniola (trunk). Phylogenetic studies using mitochondrial DNA indicate that the same ecomorphs have evolved independently on each island, i.e., they appear to have arisen as a result of one-to-one convergence of the same set of ecomorph types on each island (Losos, 1992). However, the sequence by which they evolved differs on each island. Such tests of convergence are among the strongest available for evaluating the premise that the number and types of coexisting species are locally determined. The conclusion from this research was that “adaptive radiation in similar environments can overcome historical contingencies to produce strikingly similar evolutionary outcomes” (p. 2115, Losos *et al.*, 1998).

Sticklebacks in Deglaciated Lakes of Canada

Deglaciated lakes of coastal British Columbia, Canada, harbor a tremendous diversity in the form of undescribed sibling species of fish. There are numerous examples of species pairs in many fish families, and the repeated occurrence of such sympatric pairs has been attributed to novel ecological opportunity provided by deglaciation and recolonization from relatively depauperate faunas. In particular, the radiation of species of three-spined sticklebacks (a species complex currently classified under *Gasterosteus aculeatus*) includes some of the youngest species known—less than 13,000 years. No more than two species occur in any one lake, but pairs of species in different lakes appear to have evolved completely independently of other pairs. Results based on morphological, ecological, and molecular data suggest that species have diverged as a result of parallel bouts of selection for alternate trophic environments (Figure 10; Taylor *et al.*, 1997). Natural selection has been implicated as the major cause of evolution (Schluter, 1994; Schluter and McPhail, 1993). This study has been very important in highlighting the role of divergent natural selection as a mechanism underlying adaptive radiation—a view held widely by naturalists in the earlier part of the century although, until recently, without much support (Schluter, 1996). Ecological character displacement appears to

Figure 10 Ecological divergence in sticklebacks. A1–A6 are anadromous populations, F1 and F2 are populations resident in freshwater streams, and F3 is a solitary lake population. Benthic and limnetic species of fish are shown for Paxton, Priest, and Enos Lakes. Adapted from Taylor EB, McPhail JD, and Schluter D (1997) History of ecological selection in sticklebacks: uniting experimental and phylogenetic approaches. In: Givnish TJ and Sytsma KJ (eds.) *Molecular Evolution and Adaptive Radiation*, pp. 511–534. Cambridge: Cambridge University Press.

underlie diversification in the sticklebacks, with the evolution of reproductive isolation a by-product of resource-based divergent natural selection.

Hawaiian *Tetragnatha* Spiders

The long-jawed, orb-weaving spider genus *Tetragnatha* comprises 295 described species worldwide. The adaptive radiation of the genus in Hawaii has been uncovered only recently, with a total of 28 species described and many more undescribed (Figure 11; Gillespie *et al.*, 1998). This radiation spans a huge spectrum of colors, shapes, sizes, ecological affinities, and behaviors. Phylogenetic analyses have been performed on the “spiny-leg” clade of Hawaiian *Tetragnatha*, a lineage that has adopted a vagile, cursorial predatory strategy. On each island, species can be characterized as “green leaf-dwelling,” “maroon,” and “gray/black bark-dwelling.” However, species on any one island are generally most closely related to each other, and each of the different ecomorphs appears to have evolved independently on the different islands (Gillespie *et al.*, 1997). There appears to have been a one-to-one convergence of the same set of ecomorph types on each island.

Hawaiian Swordtail Crickets

Thirty-five species of *Laupala* (Gryllidae) are found in rain forests across the Hawaiian archipelago, and up to 4 species

Figure 11 Adaptive radiation of Hawaiian *Tetragnatha* spiders. Shown are representative species from a lineage that has abandoned web building (“spiny-leg” species) and a large lineage of web-building species that show tremendous morphological and ecological diversity. Spiny-leg species: From top, *T. brevignaiha* and *T. kamakou* from wet forests on E. Maui; *T. pilosa* from wet forests on Kauai. Web building species: Five from wet forests on E. Maui (clockwise from bottom left): *T. filiciphilia*, *T. stelarobusta*, *T. paludicola*, *T. eurychasma*, and *T. trituberculata*; (bottom right) undescribed species from wet forests on Hawaii.

coexist on any given island (Otte, 1994). In common with other crickets, courting males “sing” to attract females by rubbing their forewings together. Each species has a unique song, and females respond preferentially and move toward the source of their species-specific song. It appears, therefore, that the song serves as an important mate recognition signal and variation in the acoustic system may serve as a basis for behavioral isolation between species. Phylogenetic analyses based on morphological (Otte, 1994) and molecular (Shaw, 1996) characters indicate that extensive inisland species formation has occurred in this group. Differentiation between closely related species is associated with changes in song. These features of the *Laupala* system suggest that, unlike the Hawaiian *Drosophila*, founder events have not played a major role in the initial stages of species diversification (Shaw, 1996). Rather, differentiation appears to occur through the interaction of sexual selection on genetically well-structured populations. More work is needed to understand the relative importance of these factors in the initial divergence of species in this group.

Partula Land Snails

Land snails can exhibit tremendous phenotypic polymorphism with respect to the color, banding, and chirality of the shell. *Partula* is a group of species inhabiting the volcanic islands of the South Pacific. The evolution of this group parallels the geological history of the islands. They provide an example of classical

adaptive radiation and also show that changes in ecologically important traits need not be accompanied by large genetic changes, and that the ecological changes can take place before reproductive isolation is complete (Johnson *et al.*, 1993; Murray *et al.*, 1993). Competition appears to be important in dictating the array of species at a site.

Bacteria in Culture

As described previously, experimental studies on a bacterium, *Pseudomonas fluorescens*, have provided fascinating insights into possible processes underlying adaptive radiation. *Pseudomonas fluorescens* was found to diversify rapidly from an isogenic population under conditions of environmental heterogeneity. Moreover, selection appeared to be the primary force maintaining diversity in the heterogeneous environment. The evolution of variant forms was found to follow a predictable sequence (cf. Caribbean lizards, stickleback fish, and *Tetragnatha* spiders), and competition is inferred to maintain the variation (Rainey and Travisano, 1998).

Conclusions

Three primary mechanisms have been inferred to underlie species proliferation in adaptive radiations: (i) geographical differentiation and subsequent character displacement (on the

basis of either ecologically or sexually important characters) in Galapagos finches and African cichlids; (ii) sexual selection, with or without genetic bottlenecks, in Hawaiian *Drosophila* and *Laupala* crickets; and (iii) divergent natural selection based on ecological shifts in Hawaiian *Tetragnatha* spiders, plants in the Hawaiian silversword alliance, lizards in the Caribbean, *Partula* land snails in the Pacific, stickleback fish in deglaciated lakes, and bacteria in culture.

The Future

Adaptive radiation, as a phenomenon, has tremendous research potential: The existence of a suite of closely related species adapted to exploit different habitats or lifestyles allows one to make comparative studies on the processes of speciation and selection in natural populations. Molecular systematics is providing a much better understanding of the evolutionary history of groups of closely related species and provides the opportunity for testing mechanisms underlying adaptive radiation (Givnish, 1997). The phylogenetic hypotheses provide a framework for examining the evolution of specific morphological, ecological, behavioral, and physiological adaptations and the circumstances in which they have arisen and have allowed adaptive radiation.

Adaptive radiations have recently become the focus of studies in conservation biology because they are frequently, particularly on islands, associated with high frequencies of endemism. As a corollary to the high endemism, many of the species that make up an adaptive radiation are often very rare and are characterized by very high extinction rates. Far more extinctions have been documented from islands than from continents: Of known extinctions, those from islands comprise 58% for mammals (most of which are absent from remote islands), 80% for mollusks, and 85% for birds (Whittaker, 1998). Similarly high extinction rates are known for radiations of lacustrine fish. The high rate of extinction of these narrowly endemic species has been greatly accelerated in recent years by the introduction of alien species into island environments. The plight of these extraordinary sets of species has largely been ignored because attention has focused on the devastation of forests in South America and Asia. However, setting aside even small reserves would serve to protect many species on islands from extinction. The microcosmic nature of species swarms makes such efforts at least feasible. However, without immediate action, few of the world's most spectacular radiations will survive far into the next millennium.

Glossary

Biodiversity A measure of the relative abundance of species or higher taxonomic units found in a certain area at a particular time. In ancient communities, this is often simply referred to as the number of species or taxa found at a site, usually referred to as “species richness” in the ecological literature.

Community A group of interacting organisms, representing multiple species in a given location.

Complex adaptive systems A group of individuals or types that exhibit variability in which large-scale patterns emerge from small-scale interactions. The system is adaptive in the sense that it is subject to extrinsic selection that leads to a change in structure and dynamics over time.

Evolution The morphological or genetic change in species over time. Small changes that do not lead to reproductive isolation among members of a group are referred to as “microevolution.” Speciation, or the generation of new species, is generally referred to as “macroevolution.”

Fossil Anything found in a strata of rocks or sediments that is recognized as the remains of an organism from a former geological time.

Species A group composed of individuals that interbreed or potentially interbreed and are separated reproductively from other such groups.

Taxon (taxa) A group of individuals representing a classification of organisms, such as genus, family, or order. Higher taxa are those above the species level.

Introduction

The earliest record of life on Earth is from approximately 3.6 billion years ago. Aside from the various hypotheses as to how life arose, a topic beyond the scope of this article, the fossil record clearly reveals that early life forms were single-celled organisms of the group Archaea with structures similar to modern bacteria. The Earth at that time was far different than today and would have been uninhabitable to the vast majority of the contemporary species. Our understanding of these life forms that have arisen over this time to the present relies mainly on the fossilized remains of organisms representing an array of groups that far exceeds those living today. Estimates for the diversity of life on Earth, based on the small sample of discovered fossils, suggest that greater than 99.9% of species have evolved and disappeared through extinction. Although the fossil record contains discontinuities and absences of these taxa, evidence is more than sufficient to reveal the evolution of the diversity of life and even provide details in the changing of communities, or groups of species, over time. This level of detail is astounding, but it is only suggestive of far greater details likely to be uncovered in the coming decades. In addition, recent development and use of computer models is enabling us to both understand these paleobiological data and make predictions of how evolution influences the dynamics of communities over time. The author suggests that the coupling of our rapidly increasing knowledge of the fossil record and our use of computer modeling will help us to both understand and predict the influence of humans on the patterns of biodiversity.

The Fossil Record

What Does the Fossil Record Indicate?

In general, the fossil record is an outstanding record of the changes in biodiversity, revealing both an increase and

turnover in taxa over time. Data for marine organisms suggest that the diversity of families has generally increased during the Phanerozoic, which includes the past 540 million years (My), the time for which fossilized remains of multicellular organisms exist (Figure 1; Sepkoski, 1991). A broader survey suggests that diversity has increased almost exponentially for all known families, genera, and species during this period

Figure 1 The diversity of skeletonized marine animal families during the Phanerozoic. The bold line represents total numbers of families known from the fossil record. Five major extinction events are indicated: 1, end Ordovician; 2, Late Devonian; P, end Permian (largest); 3, end Triassic; 4, end Cretaceous. V, Vendian; C, Cambrian; O, Ordovician; S, Silurian; D, Devonian; C, Carboniferous; P, Permian; Tr, Triassic; J, Jurassic; K, Cretaceous; T, Tertiary. Faunal assemblages are categorized as Cm, Cambrian; Pz, Paleozoic; and Md, Modern. Reproduced from Sepkoski Jr. JJ (1991) Diversity in the Phanerozoic oceans: A partisan review. In: Dudley EC (ed.) *The Unity of Evolutionary Biology*, pp. 210–236. Portland, OR: Dioscorides Press.

Figure 2 Diversity has increased exponentially for all known families, genera, and species during the Phanerozoic. The top and bottom lines represent maximum and minimum numbers of families, respectively. See the legend to **Figure 1** for abbreviations. Reproduced from Benton MJ (1995) Diversification and extinction in the history of life. *Science* 268: 52–58.

(**Figure 2**; Benton, 1995). More recently, works by Courtillot and Gaudemer (1996) and Pave *et al.* (2002) have argued that biodiversity has increased logistically, with a relatively rapid increase followed by a leveling of diversity over time (see **Figure 1**).

Increases in taxa, however, have been discontinuous, with major catastrophic losses of taxa in the form of mass extinctions, such as that which occurred at the end of the Cretaceous period that led to the loss of the dinosaurs. Thus, the accumulation of biodiversity in the form of numbers of taxa has been discontinuous and has exhibited a skewed distribution in the magnitude of the size of extinction events, ranging from relatively low-level background extinction rates to large-scale mass extinction events.

In general, we know that species are generally shortlived, averaging a duration on the order of 5 My, with few taxa being long-lived. Most species are, and are inferred to have been, composed of relatively few individuals which are locally distributed and few species being relatively abundant and widely distributed. We also know that most genera have few species, whereas most families have few genera. These patterns have led and continue to lead to high probabilities that any particular taxon is likely to be relatively short-lived as opposed to long-lived, where the mean duration of taxa exceeds the median duration.

The Number of Taxa has Increased over Time

A clear and dramatic trend exists in the fossil record of an increase in diversity. This pattern exists for taxa ranging from the level of species to phyla, and it has been well documented for plants, invertebrates, and vertebrates. This pattern is seen, for example, in the number of marine families over time during the Phanerozoic eon, since about 540 million years ago (**Figure 1**). The major additions to diversity in the fossil record include skeletonized marine invertebrates during the Cambrian, especially trilobites, brachiopods, and archaeocyathans. Corals, cephalopods, ostracods, crinoids, and starfish arose

Figure 3 The number of large mammal species from North America during the past 44 million years. Note the correlation between the diversity of predators and their potential prey ($r^2=0.43$; $p<.001$). Data from Van Valkenburgh B and Janis CM (1993) Historical diversity patterns in North American large herbivores and carnivores. In: Ricklefs R and Schluter D (eds.) *Species Diversity in Ecological Communities: Historical and Geographical Perspectives*, pp. 330–340. Chicago: University of Chicago Press.

through the remainder of the Paleozoic, and bivalves, gastropods, echinoids, teleost fish, and marine reptiles arose during the Mesozoic. Diversity increased on land and included the evolution of vascular plants (Silurian and Devonian), gymnosperms (Carboniferous), and angiosperms (Jurassic). Insect diversity exploded in the late Paleozoic, followed by social insects in the Jurassic. Major clades of terrestrial vertebrates arose by filling vacant niches, including amphibians (Devonian), reptiles (Carboniferous), pterosaurs and dinosaurs (Triassic and Jurassic), birds (Jurassic), and mammals in the early Tertiary.

The pattern, however, is one of fluctuations over time in the shorter term. The number of species of relatively large herbivores and carnivores in North America during the past 44 My, for example, appears to exhibit little long-term trend toward increased or decreased diversity (**Figure 3**). Interestingly, however, these data suggest that the number of predators depends on the number of potential prey species over time. There is a significant correlation between the number of predators and preys which is consistent with the hypothesis that interspecific associations are interdependent within communities over time.

Extinction Events are Followed by Evolutionary Radiations

Extinction and the origin of species define the dynamics of the fossil record. Species, for instance, typically last on the order of 1–10 My and appear to go extinct in a nonrandom fashion. Therefore, species arise and ultimately disappear throughout time, producing a general pattern of loss referred to as “background” extinction (**Figure 4**).

Biodiversity at various levels of organization has increased during the Phanerozoic. There exist, however, at least five catastrophic extinction events that have led to a decrease in the number of taxa, and therefore biodiversity, that greatly exceed the background extinction rate (**Figure 4**). In particular, the extinction event at the end of the Permian (**Figure 1**, “P’)

Figure 4 Background and mass extinction of marine animal families during the Phanerozoic. Rates are reported as the number of families lost per million years. Extinctions within dotted lines represent background rates, whereas solid lines above the upper dotted line represent mass extinctions. Mass extinctions: ASHG, Ashgillian (end Ordovician); GIV, Givetian; FRAS, Frasnian; FAME, Famennian (Late Devonian); GUAD, Guadalupian; DZHULF, Dzhulfian (end Permian); NOR, Norian (end Triassic); MAEST, Maastrichtian (end Cretaceous). For other abbreviations, see the legend to **Figure 1**. Reproduced from Raup DM and Sepkoski Jr. JJ (1982) Mass extinctions in the marine fossil record. *Science* 215: 1501–1503.

resulted in a loss of a maximum estimated 96% of species on Earth (although this is likely an overestimate; Raup, 1994).

The overall pattern of extinction appears to follow a well-defined “kill curve,” proposed by Raup, that indicates a skewed distribution of species loss ranging over the gradient where most time periods exhibit low rates of extinction (background) and few periods of very high rates of extinction (mass extinctions). These data, therefore, suggest a predictable pattern, based on probability, that describes species extinctions.

Following extinctions there is general radiation, or rapid evolutionary diversification, of taxa. This is seen in Sepkoski’s database of marine families (**Figure 1**) and even more clearly in Benton’s larger database of families from both terrestrial and marine systems following the five major extinction events (**Figure 2**).

The rates of species origination have varied over time and are highest following periods of mass extinction and in times when new ecospace became available, such as during the initial rise of diversity during the late Vendian and Cambrian (**Figures 1** and **2**). Speciation was highest for terrestrial families during the Priabonian (late Eocene), most likely due to the increase in insect diversity.

How Good Is the Fossil Record?

The fossil record is far from a complete representation of all of the Earth’s biotic history. There are only bits and pieces of evidence from organisms and we are able to date strata from which organisms derive only with varying levels of accuracy. The fossil record is better, in general, for recent strata and decreases in completeness with age. The fossils we do have, however, enable us to construct a logical progression in both

complexity of form and diversity over time. The idea that evolution is progressive, however, has long been abandoned in light of the many examples of lineages that do not follow straight progressions of simple to more complicated forms over time. Moreover, extant species that appear ancient, such as the coelacanth, horseshoe crab, and cockroach, are neither unchanged from their ancestors nor are their longevities unexpected. By chance we can expect variance in the longevity among lineages, with many short-lived species and few long-lived species.

Understandably, only certain morphological characteristics have been susceptible to fossilization. Of those that are fossilized we often find only disarticulated parts of organisms, such as a tooth, part of a shell, or perhaps a bone fragment, separated over varying distances. Soft-bodied organisms and soft tissues are rarely observed. To complicate matters, these fragments are susceptible to movement both spatially (e.g., down-stream after death) and vertically in the stratigraphy, which makes fossils appear to move temporally. This occurs when sedimentation rates are very low, allowing noncontemporaneous organisms to become fossilized together, or when layers are mixed or folded, a process referred to as “time averaging” of the fossil record. However, taphonomy, or the study of postmortem behavior of organic remains, indicates that a vast majority of organisms are not transported out of their original habitats and therefore can be used to construct probable past communities. Evidence for this derives primarily from the observation of contemporary local death assemblages in which individuals rarely move across community boundaries.

Microfossils such as pollen are abundant in lake sediment and can be used for quantitative reconstruction of local plant communities. Pollen from sediments on the order of a few hundred thousand years has been used to reasonably describe assemblages. Little is known about the role that evolution played in plant communities from sediments more than 1 My old. The pollen record during the Holocene (e.g., since the past glacial period ended about 16,000 years ago) has been widely and more confidently used to reconstruct past plant communities. Therefore, we remain perplexed with regard to the various assemblages of taxa that likely resided concurrently in more ancient communities, but for more recent times we have increasing confidence in our effort to reconstruct communities from fossil remains.

What Does the Fossil Record Indicate About Communities?

The interpretation of community structure in the fossil record is more problematic than documenting the change in taxa over time. The primary difficulty lies in determining whether fossilized taxa occurred contemporaneously. Postmortem movement of organisms and their parts appears to take place over relatively short distances and within time-averaged ranges of species, which is a pattern found for both marine and terrestrial taxa. Therefore, optimistically, it appears that co-occurring taxa through the fossil record will likely represent evidence of past communities.

Evidence from pollen records, however, can produce a paradox in our interpretation of past plant communities. Over long periods of time, pollen deposition in lake sediments

generally reflects nearby plant communities accurately. The distance-dependent deposition of pollen is generally correlated with the sum basal area of trees (cross-sectional area of tree diameters) within a few square kilometers of the surrounding area, although many factors influence the pollen collected from lakes and the surrounding vegetation, such as relative decomposition rates and the relative efficiency of a lake to capture pollen. Pollen records from lake sediments, however, suggest that the composition of plant species changes over time and that the species change independently of each other in response to rapid climate change following the Wisconsin glacial period in North America. In addition, there is a consistent pattern that, among late Quaternary pollen records for basins of different sizes and from different regions (temperate and tropical), communities appear to be the product of independently acting species.

The rain of leaf litter and other debris, likewise, is well correlated in contemporary communities with the abundance of trees within local communities. Unfortunately, leaf litter, in general, rapidly decomposes and rarely provides evidence of past communities.

The fossil record remains difficult to interpret with regards to community composition and dynamics over time. Considerable research is needed and is under way on the dynamics of communities over long periods of time. In particular, we need to resolve conditions that lead to the following paradox: Taphonomy of current assemblages suggests fossil taxa may represent contemporaneous communities, whereas pollen studies suggest that at least plant species have acted relatively independently over time. Additional data are needed to help reconstruct the composition of past communities accurately. In addition, the expanding use of detailed DNA sequence data will undoubtedly help to resolve phylogenetic relationships over evolutionary time.

Current Patterns of Biodiversity

Biodiversity is heterogeneously distributed on Earth, with the general pattern that species diversity is greatest near the equator and decreases with increasing latitude. Hypotheses and evidence for these patterns abound. In the following sections, the author briefly introduces how we define biodiversity, discuss very general trends in communities, and apply these to understanding biodiversity of communities over time.

How do we Define Biodiversity?

Before discussing patterns of biodiversity change over time, the author needs to define diversity. In general, paleontologists consider biodiversity to be equivalent to the number of unique taxa. In the ecological literature, diversity generally incorporates both the number of species and equitability or the relative abundance of individuals among species. A simple hypothetical example is the relative diversities of two communities. Assume that both have 100 individuals within two species. One community has 99 individuals of one species and the second community has 50 individuals of both species. The first community is essentially a monoculture of species 1. The

second community is considered a more diverse community, despite the fact that both communities have the same number of species present.

Accounting for equitability in the fossil record, however, is quite problematic because of the spotty nature of the preserved specimens. It must be recognized that fossils in an assemblage will not likely constitute a random sample of individuals from a community. Rather, the remains of fossil communities are likely to be composed of a skewed distribution of individuals representing only a subset of those species that contained structures susceptible to fossilization. Other species possibly escaped fossilization completely or were missed in the sample from which the fossils were found. In addition, the subset that is found is more than likely to be small and therefore highly susceptible to the variance incurred from the chance occurrence of individuals of rare species. This is an example of the problem referred to as the “central limit theorem” in statistics in which sampling of a skewed distribution (the reality of the fossil communities) yields a normally distributed population (not an accurate representation of the fossil communities). In other words, we are most likely to find fossils of the most abundant species, yielding an underestimate of the true number of species that occurred at that time in that community. Some fossil assemblages, however, will contain samples of relatively rare taxa, making these taxa appear more abundant than they really were. In addition,

it is difficult to assess whether forms represent truly different taxa. We are more likely than not to lump taxa together because of our inability to know whether similar fossils represent members of an interbreeding population.

Patterns of Species Change Over Time

Simple change in the number of species over time can be expressed as a rate, similar to the change in a population over time. We can represent this change in the number of taxa over time as $dN/dt = RN$, where N represents the number of species in a genus or genera in a family, and $R = S - E$, where S is the speciation rate and E is the extinction rate. We may therefore assume $dN/dt = 0$ to represent a null hypothesis against which we test for significant changes in the rates of species additions or subtractions. There are several problems with this approach, however, since our null hypothesis is that all species are expected to eventually become extinct. Therefore, we must define a time constraint of interest, concluding that if $R < 0$, then the taxa of interest appear to be on the decline. Comparisons of the fossil record have been found to differ from this random null hypothesis. The database assembled by Sepkoski (Figure 1) suggests that diversity increases logistically, whereas the data set assembled by Benton (Figure 2) suggests diversity has increased exponentially during the past 600 My.

The work previously mentioned by Courtillot and Gaudemer (1996) and Pave *et al.* (2002) suggests that exponential growth for species number over time might not be supported by the data. These analyses are challenging, however, in the light of imagining the mechanisms that would bring about regulation in the number of species over time.

Are Communities Saturated with Species?

In general, it appears that many communities are at or near a saturation level for the number of species they contain. The evidence for this derives indirectly from several sources, including the relationship of families depicted previously in the fossil record and from the ecological literature in which is found a general inability of introduced species to successfully invade communities. Species introductions usually fail, and when they succeed, the species usually have little consequence on natural systems, despite the numerous celebrated examples of introduced species altering native communities. Occasionally, even with the loss of native dominant species such as the American chestnut tree to a fungal blight, the effect on natural processes may be equivocal.

The result of this contemporary observation suggests that communities may reach taxa saturation. If this pattern holds for prior paleocommunities, then this suggests that ecological and evolutionary processes operate to fill available niche space with either colonizing species or through the process of speciation. Inspection of either Sepkoski's or Benton's databases for the number of taxa over time suggests that the Earth is not at a carrying capacity. The following is the obvious question stemming from this: Where should we expect to find new species occurring, especially in light of the estimation that humans are currently consuming approximately 40% of the Earth's productivity?

Community Stability

Researchers in the field of ecology, and particularly conservation biology, have long been interested in the dynamics of communities and the rate of species change over time, also referred to as "species turnover." Hutchinson and his student MacArthur were early advocates of the notion that stability of communities is positively related to the number of species residing in the community. This relationship, quantified by MacArthur and incorporated into the influential theory of island biogeography developed in collaboration with Wilson, portrayed ecological systems as having stable equilibria, resulting from the trade-off between colonization and extinction rates on islands. Recently, this theory has been extended to systems that, in general, function like islands.

Although intuitively attractive, the positive relation between diversity and stability may not be universal. In addition, researchers have to assess the role diversity plays in community dynamics differently. For instance, in 1973, May suggested that there may be an inverse relationship between species diversity and community stability in model food webs, as measured by the long-term maintenance of species composition. Alternatively, research by Tilman on grasslands in Minnesota suggests that community resistance to drought, as measured by the maintenance of productivity, is positively related to the number of species in the community. These results suggest a complex interplay between diversity and various measures of stability. Understanding the role of diversity on the functioning of ecosystems is of particular concern as we face rapid changes in our global climate.

Communities as Complex Adaptive Systems

Recent developments in our understanding of community assembly, organization, and development over ecological and evolutionary time suggest that communities are more complex than previously believed. Classic approaches to understanding the dynamics of communities portrayed them as being composed of individual species that interact ecologically with little regard to spatial location or temporal dynamics. Recently, we have come to appreciate the intricacies of small-scale spatial and temporal partitioning of resources and interactions among co-occurring organisms. In addition, in the past 30 years we have come to appreciate the immense genetic diversity within species that enables species to adapt to biotic and abiotic factors that operate spatially within communities (Thompson, 1994).

Complex adaptive systems can be defined as groups of individuals that exhibit variability, interact with a subset of individuals within the global population (usually within some local neighborhood), and are susceptible to an autonomous, selective process that usually leads to individuals experiencing differential reproduction. These rules apply quite generally to species, communities, and other systems such as economies, allowing them to adjust to changing environmental conditions. Natural communities fit this general class of systems very well, and recent theoretical work has described the similar dynamics among diverse systems. Recent work, for instance, suggests that population and community dynamics may be influenced by the process of evolution acting on genetic diversity among individuals (Hartvigsen and Levin, 1997). It is likely that this new theoretical approach will lead to a greater understanding of how communities respond evolutionarily to disturbances over time scales greater than years.

The Effect of Disturbance on Community Biodiversity: Evolutionary versus Ecological Time

The causes of various mass extinction events are not known, but hypotheses do exist. The most recent mass extinction at the end of the Cretaceous was most likely caused by an asteroid impacting the Earth, forming the Chicxulub crater on the north side of the Yucatan Peninsula. The causes of the other mass extinctions are unresolved but may be the result of similar massive disturbances. The probability distribution of taxa loss appears to follow what we expect to occur by chance and matches the loss of taxa due to random factors. Occasionally, we should expect to lose many species, whereas over most time periods, only a few species should be expected to be lost. Therefore, the greater the disturbance, the greater the effect (reduction) on biodiversity.

The probability of species loss depends on many factors, including the size of the populations of species within the community. Smaller populations are more likely to go extinct than larger populations, a process referred to as demographic stochasticity. The Gambler's Ruin is a metaphor that is commonly associated with this process. The idea is that a gambler in a casino who has a limited number of betting units to lose (e.g., quarters for a slot machine or equivalents to the minimum bet at a black jack table) is more likely to go bankrupt simply by chance compared to a gambler with many betting

units. Likewise, stochastic, or random, changes in population size lead to small populations being more likely to reach the absorbing state of zero individuals than a large population. Therefore, and not surprisingly, small populations are at the greatest risk of extinction simply by chance.

Communities composed of species with small populations are therefore likely to suffer higher levels of species loss than communities composed of species with large populations. Raup (1994) argues that there appears to be little predictability in which species will be eliminated and that extinction does not appear to be selective. Species with narrow geographic ranges may be more susceptible to extinction, whereas species with large geographic ranges are not likely to experience disturbances so great as to influence their entire population.

Small populations typically exhibit lower genetic variability than large populations and are more likely to become locally extinct. Small populations, however, may experience more rapid evolution due to reduced genetic inertia. This may be seen in the founder effect, in which a few individuals begin a new population leading to allopatric speciation.

Without knowing the probability distribution of extrinsic factors causing large-scale mass extinctions, it is difficult to extrapolate from the fossil record if the species that went extinct in fact had small populations. In addition, it does not appear that evolution during the past several hundred years has reduced the likelihood of extinction events. There is no clear reduction in the apparent risk of such mass extinctions with time in the fossil record. Using the “all things being equal” assumption, the fossil record (Figures 1 and 2) suggests that, with a general trend toward increased diversity over time, the condition of having more taxa should lead to increases in the number of taxa lost due to disturbances. That is, if the probability of extinction of any particular species is constant, then we should see increased extinction rates as diversity has increased. However, as shown in Figure 4, the background extinction rate appears to have decreased with time. There remains the need to evaluate the risk of extinction by determining factors such as the absolute abundance of individuals within species and how this influences the extinction risk. For example, if increased diversity over time has led to smaller population sizes due to the ecological partitioning of resources, we may anticipate a trend toward increased extinction rates.

Experimental work on laboratory and field communities suggests that decreasing biodiversity also leads to a reduction in ecological time of ecosystem function, such as total productivity and carbon dioxide sequestration (Tilman and Downing, 1994; Naeem *et al.*, 1994). More recently Oswald and Steadman (2011) published data that suggested that the extinction of a cowbird (*Pandanus convexa*) during the Pleistocene was associated with the extinction of large herbivores. These examples support the idea that positive feedback mechanisms may operate so that disturbed communities are more likely to lose species in addition to those initially lost due to decreased population size.

Models of the Influence of Evolution on Ecological Systems

The effect of evolution on the likelihood of species extinction and community stability represents a fundamental problem in

the field of evolutionary ecology and is of great importance to our ability to conserve species over long time periods. Theoretical work suggests that the process of evolution influences population and community dynamics (Hartvigsen and Levin, 1997; Doebeli, 1996). Hartvigsen and Levin, using a spatially explicit individual-based model that accounts for genetic variability at the individual level, leading to evolution over time, show that the process of evolution in a model system can slow population dynamics, suggesting that the risk of species extinction declines due to reduced fluctuations resulting from demographic stochasticity. If this occurs in real systems, then we might expect a positive feedback mechanism to operate such that a population reduced in size is likely to experience a loss in genetic diversity. In addition to other known factors that increase the extinction risk of small populations, including inbreeding depression and social dysfunction (Allee effect), a loss in genetic diversity may increase population fluctuations, thus increasing the likelihood that such a species will go extinct.

The Future Record

Documenting Earth's Current Mass Extinction Event

The extent of the current extinction event will only be known in retrospect. However, there are patterns that are recognizable today. For example, there exists a good record of species that have gone extinct during the past 400 years (Smith *et al.*, 1993). A minimum of 485 animal species and 584 plant species became extinct during this period, with approximately half of these occurring during the twentieth century. This includes the loss of nearly 1% of all known bird species during the past 100 years, mostly due to human activity. This loss suggests an average species duration of about 10,000 years, which is two or three orders of magnitude shorter than has occurred on average in the fossil record (in other words, this represents an extinction rate two or three orders of magnitude greater than the background extinction rate in the fossil record). It is this rate of known extinction, compared to average extinctions in the fossil record, that suggests humans are the impetus for a mass extinction event.

More troubling is a recent analysis of extinction rates in amphibians which suggests that the current rate of loss dwarfs the background extinction rate observed in the fossil record (over the past several major extinction events). This rate may even be, since 1980, several orders of magnitude greater than seen previously (McCallum, 2007).

The Big Question: How Will the Process of Evolution Influence Biodiversity Dynamics?

Evolution generates new species in the aftermath of mass extinction. This is well supported by the fossil record and appears, in geological time, to be rapid. The current extinction event taking place on Earth, however, appears to be more rapid than has occurred previously (Smith *et al.*, 1993). Speciation will undoubtedly lead to the rise of new taxa but over time scales that are likely to be too long to have a noticeable effect in our lifetime. In addition, and more troubling, is the suggestion that

relatively young taxa are likely to be more susceptible to extinction due to the smaller population sizes and the relatively limited geographic ranges (Boyanjian, 1991).

The other role that evolution plays in biodiversity is its ability to influence the stability of communities. Little is known about this role of evolution. Empirical data for plant communities suggest that stability is correlated with biodiversity, such that more diverse communities are more resilient to disturbance. Natural communities are often composed of genetically variable individuals, which provide the foundation that enables species to evolve in response to biotic and abiotic factors over time. Also, communities with more species are in general more diverse genetically. If the time frame of environmental change can be matched by selection operating on genetic diversity, communities may resist disturbances by adjusting to changes over time. The analogy of species wandering over an “adaptive landscape” (sensu Sewall Wright) produces an image of communities functioning as complex adaptive systems. Ecosystems that function as complex adaptive systems may resist environmental fluctuations. If, however, environmental disturbances are abrupt, communities may either not be able to react quickly enough or suffer overloads that essentially shake species out of the community. There is evidence that communities harbor redundancy at the species level, but we have not yet determined patterns that identify which species are necessarily important or unimportant for community function. Therefore, the loss of species from communities is likely to decrease, if only slowly, the stability of communities.

Theoretical work suggests that the process of evolution may increase the resilience of communities to disturbance. This area of inquiry is in its infancy and will likely become an important and rapidly developed discipline in the following decades.

Conclusion

Biodiversity, measured as the number of taxa, has increased on Earth over time. This pattern appears to follow either an exponential or a logistic growth pattern of taxa during the past 540 My. The increase in taxa, however, has been discontinuous due to extinction events. There appears to be a probability distribution of extinctions with small background extinctions occurring frequently and large catastrophic mass extinctions occurring rarely. Biodiversity has repeatedly and rapidly rebounded following such extinction events.

Biodiversity currently appears to be near a saturation level, based on the observation that most species that are introduced to areas fail to successfully become established. However, the pattern of increase in the number of taxa (e.g., families) over time does not appear to be at or near an asymptote (Figure 2). The extreme alteration of the earth’s biosphere by humans is likely to lead to a mass extinction event, currently on the order of 10–100 times the background extinction rate observed in the fossil record. In areas where habitats are disturbed rather

than destroyed, an explosive radiation of new species may occur, manifested, however, only over geological time.

The process of evolution may help stabilize communities. However, current human-induced worldwide disturbances are likely to lead to reduced population sizes and a resulting loss in genetic diversity, ultimately increasing the likelihood that more species will go extinct.

Glossary

Cambrian explosion A period of about 25 million years during the Cambrian, when the diversity of multicellular life greatly increased in a relatively short time.

K-T event A notable large-scale extinction event occurring about 65 million years ago, at the boundary of the Cretaceous and the Tertiary, involving the extinction of about 70% of extant species, including the dinosaurs and many other land-dwelling vertebrates.

Monograph effect A term for the fact that the apparent existence of intensive evolutionary activity in a given interval actually reflects the fact that researchers have thoroughly studied a particular section of the fossil record

which reveals this activity, while other such investigations elsewhere might just as well have produced the same number of previously unknown species.

Pull of the recent A term reflecting the fact that recently formed rock is more accessible and offers better preserved fossils; this may produce a bias toward the conclusion that diversity has increased toward the present time.

Taxon sorting The argument that in certain taxa, species undergo relatively rapid speciation and extinction, while in others the species speciate and die out relatively slowly; over time this difference will mean that the highly volatile families become extinct more quickly than the less volatile ones.

Life began on Earth about 3.5 billion years ago in the Archean Eon, probably with the appearance first of self-reproducing RNAs and later of prokaryotic single-celled organisms. No actual fossils date from this far back, and so our knowledge of Archean life is sketchy at best. Approximately 2.5 billion years ago the last stocks of elemental iron in the earth's crust were converted to oxides as a result of photosynthesis by cyanobacteria, and the planet's atmosphere changed from reducing to oxidizing, making oxygen-breathing life possible. The Proterozoic Eon which followed saw the first appearance of eukaryotes (organisms with nucleated cells and mitochondria), sexual reproduction, and multicellular organisms, although the precise timing and even the order of these innovations are disputed. The earliest firm evidence of metazoan multicellularity dates back to about 575 million years ago.

The end of the Proterozoic at the Vendian–Cambrian boundary about 545 million years ago marks the start of the Cambrian explosion, a period of approximately 25 million years during which, for unknown reasons, multicellular life underwent a period of extraordinary diversification, producing a multitude of new evolutionary lineages in a comparatively short time, including almost all of the major metazoan body plans seen today as well as many which have become extinct. The fossil record from the Cambrian onward—an interval known as the Phanerozoic Eon—is good by comparison with that of the Precambrian largely because multicellular organisms, whose fossils are easier to find and study than those of single-celled organisms, became numerous.

The Phanerozoic fossil record consists of about a quarter of a million known species. The vast majority of these are marine species, mostly invertebrates such as mollusks, brachiopods, corals, or foraminifera as well as sea-dwelling plants. Terrestrial (i.e., land-dwelling) organisms are far less well preserved because the depositional regimes under which fossils are formed are less reliable and uniform on land. Even for marine

species, there are many biases in the fossil record, among which the following are some of the most important:

1. Deposition can vary greatly from one time to another. Even in the oceans, in which deposition is relatively reliable, there are periods during which preservation is excellent and others in which it is poor. A sudden period of poor preservation can even give the appearance of a large extinction event because the number of preserved organisms decreases substantially.
2. The “Pull of the Recent” is the name given to the greater accessibility of recently formed rock and the better preservation of fossils in these rocks. The Pull of the Recent implies that we have a more complete record of recent times than we do of times long past, and this could produce the misleading impression of an increase in diversity toward the present where none exists. Despite this bias, it is still believed (as discussed later) that there has been a real increase in biodiversity over the course of the Phanerozoic.
3. The “monograph effect” refers to the sudden apparent burst of new species resulting from the attention paid by a particularly zealous researcher or group of researchers to a particular section of the fossil record: The thorough investigation of a short interval can turn up many previously unknown species, making that interval appear to be one of especial evolutionary activity when in fact a similarly thorough investigation of another interval would have turned up just as many species. A similar effect is produced by the discovery of a particularly rich and well-preserved fossil bed dating from one particular time.
4. Although it is now possible to date fossils within a few million years with high confidence, more accurate dating in the fossil record is still problematic. Absolute dates are derived from slowly decaying radioactive isotopes, whereas relative dates of different fossils are derived from

stratigraphic evidence, both geological and from fiducial lineages (so-called “index fossils”). Some geographic areas and intervals of time can be dated with high accuracy—a million years or better—but others are not nearly as good.

Despite these biases, the overall pattern of life during the Phanerozoic survives the vagaries of the record and is now reasonably well understood.

Figure 1 is a graph of (marine) biodiversity as a function of time during the Phanerozoic. The horizontal axis measures time before the present, whereas the vertical one measures the number of known families of marine animals at a succession of times. Each point corresponds to one stratigraphic stage; stages are irregular intervals of time of average duration of about 7 million years which are based on widely accepted stratigraphic features. The data are taken from the compilation of marine families by Sepkoski (1992).

One of the most notable features of **Figure 1** is a substantial increase in the number of known families over the course of the Phanerozoic, particularly in the 250 million years since the Late Permian mass extinction. Overall, the number of known families increases by more than a factor of 10 from the earliest Cambrian to the present. In considering this increase, one must first ask whether it is genuine or an artifact of biases in the fossil record. As mentioned previously, there is certainly a bias occurring because of the better preservation and greater availability of fossils in more recent rocks. There is no doubt that some of the increase apparent in **Figure 1** is a result of this bias. On the other hand, the use of numbers of families as a measure of diversity, rather than species, tends at least partly to remove this bias since we need find only one species belonging to a certain family in order to establish the existence of that family at any given time. Therefore, even during periods of relatively poor species sampling, a family with a sufficiently large number of species can still contribute to our estimate of diversity. Furthermore, there are plausible biological reasons to believe in a real diversity increase: The increase seems to some extent to be the result of the evolution of organisms into new ways of life. The spread of life onto the land in the Silurian and Devonian is a particularly prominent example of this, but among marine organisms the trend is also clear. It seems reasonable to suppose that as life spreads into new environments, the total number of species (or families) which the planet can support will also increase.

Many models have been put forward for diversity increases in the fossil record. Benton (1995) suggested that the increase is an exponential one, indicating perhaps a stochastically constant rate of creation of new taxa from existing ones, with no detectable limit to ultimate levels of diversity. A more detailed analysis has been given by Sepkoski (1981), who suggested that the diversification of life occurred in three distinct phases, each typified by vigorous turnover within a particular subset of species or “fauna.” The first phase, during the Cambrian, was dominated by groups in which the rate of origination of new species was relatively high, such as trilobites, inarticulate brachiopods, and monoplacophorans. The second phase, lasting from the Ordovician to the end of the Permian, was dominated by groups with intermediate origination rates, such as crinoids, articulate brachiopods, and cephalopods.

Figure 1 The number of known marine families alive over the time interval from the Cambrian to the present (data from a compilation by Sepkoski JJ Jr. (1992) A compendium of fossil marine animal families, 2nd edition. Milwaukee Public Mus. Contrib. Biol. Geol. 83).

Finally, there was a third phase, lasting from the beginning of the Triassic up until the Recent, which was dominated by bivalves, gastropods, echinoids, and marine vertebrates—groups which have relatively low rates of origination. Sepkoski (1984) suggested that within each of the three faunas diversification proceeds initially exponentially but eventually saturates, implying the existence of equilibrium “carrying capacities” for the global ecosystem. The superimposition of this “logistic” growth within each fauna gives rise to the observed pattern of near-monotonic diversity increase in **Figure 1**. A logistic diversification model was also explored by Courtillot and Gaudemer (1996) but without allusion to distinct faunas.

An important feature of the pattern of biodiversity shown in **Figure 1** which can be explained in terms of the logistic growth model is the apparent plateau in diversity throughout the greater part of the Paleozoic, from the Late Ordovician to the end of the Permian. (The same pattern is also present in genus-level data (Sepkoski, 1997), although there is in general more fluctuation in the numbers of genera so the plateau is not as clear.) One explanation for this plateau is that it represents the saturation phase of the logistic diversification of Sepkoski’s second fauna, which continues mostly uninterrupted for approximately 200 million year until the Late Permian mass extinction. This is not the only possibility, however; it has also been suggested that the plateau is more the result of high extinction rates in the later Paleozoic than it is the result of low origination rates (Stanley, 1999). In both cases, however, the ultimate limit on diversity is presumed to be some effective carrying capacity of the ecosystem.

Another notable feature of **Figure 1** is a dip in diversity at several points, particularly at the ends of the Devonian (D), Permian (P), and Cretaceous (K) periods. These dips correspond to major mass extinctions that can be seen more clearly in **Figure 2**, which shows the percentage of extant families of marine animals becoming extinct in each stratigraphic stage of the Phanerozoic. The data are again taken from the compilation by Sepkoski (1992). We normally distinguish five major mass extinctions during the Phanerozoic. These “big five” are

Figure 2 Estimated extinction of marine animals in families per stratigraphic stage since the Cambrian as a percentage of the total number of families in existence. The arrows indicate the positions of the “big five” mass extinction events discussed in the text.

marked with arrows in **Figure 2**. A sixth period of heightened extinction is visible in the Cambrian but is thought to be primarily an artifact of sampling biases rather than a real extinction event. Many smaller extinction peaks are also apparent in **Figure 2** but are of secondary importance. The basic features of the big five events are as follows.

The end-Ordovician event about 440 million years ago appears to have occurred in two bursts, separated by about 1 million years, which between them wiped out about 85% of then living species. The event was confined to marine species since multicellular life had not yet colonized the land. Particularly affected were brachiopods, bivalves, echinoderms, bryozoans, and corals. The immediate cause of extinction appears to have been the continental drift of a significant land mass into the south polar region, causing a global temperature decrease, glaciation, and consequent lowering of the sea level, which destroyed species habitats around the continental shelves. The sea level rose again with the end of the glacial interval about 1 million years later and caused a second burst of extinction.

The Late Devonian extinction approximately 360 million years ago is complex and poorly understood. It is probably in fact composed of many separate events (as many as seven) spread over about 25 million years, including particularly notable extinctions at the ends of the Givetian, Frasnian, and Famennian stages. Overall, about 80% of living species died out in the Late Devonian. Particularly hard hit were corals, brachiopods, bryozoans, ammonoids, and fish. The causes of these extinctions are unclear. The leading theories suggest that changes in sea level and ocean anoxia, possibly triggered by global cooling or oceanic volcanism, were most likely responsible, although the impact of an extraterrestrial body such as a comet has also been considered.

The Late Permian extinction approximately 250 million years ago was the largest extinction event of all time, killing approximately 95% of marine species and about 70% of land-dwelling ones. Like the end-Ordovician event, it seems to have

been composed of two bursts, separated in this case by an interval of about 10 million years, with the second being the larger of the two. Notable extinction happened again among brachiopods, ammonoids, and corals as well as gastropods, echinoderms, and, unusually, insects. Despite an enormous amount of research of the subject, the causes of the Late Permian event are still a subject of debate. It is clear, however, that the sea level rose during this period, levels of oxygen in the oceans were low, and carbon dioxide levels were high. There is some suggestion that a cometary impact may have been involved, or a shift in ocean circulation driven by climate change, or carbon dioxide and sulfur release following large-scale volcanic activity. The Late Permian event had a profound effect on the terrestrial ecosystem which is still being felt today, a quarter of a billion years later. A particularly notable example among marine faunas is that of the bivalves, a relatively minor group during the Paleozoic that took advantage of the ecological vacuum left by the extinction to establish a solid grip on shallow-water environments, leading to their dominance over the previously very successful brachiopods.

The end-Triassic extinction approximately 210 million years ago is probably the most poorly understood of the big five extinction events. It appears to have killed about 80% of species then living, either in one burst or possibly in two separated by about 20 million years. Major extinction is observed particularly among ammonoids, bivalves, gastropods, and brachiopods. Leading theories of the causes of the end-Triassic event are ocean anoxia, massive volcanism, or possibly a bolide impact.

The end-Cretaceous event, usually called the Cretaceous-Tertiary or K-T event, has attracted the most popular interest of any extinction because it saw the end of the dinosaurs, but it was in fact the smallest by quite a wide margin of all the big five. The K-T event appears to have been a single pulse of extinction approximately 65 million years ago which wiped out about 70% of all species then living. In addition to the dinosaurs, it extinguished many other land-dwelling vertebrates, especially large-bodied ones, along with large numbers of (marine) bivalves, gastropods, and foraminifera. The proximal cause of the K-T event was almost certainly the impact of a large comet or meteor near the present site of the town of Puerto Chicxulub on the Yucatán peninsula in eastern Mexico, with an associated drop in sea level and possibly short-term cooling or heating or acid rain. It has also been noted that average extinction rates were higher than the historical average for some time in advance of the K-T boundary, indicating that long-term environmental change may also have played a part.

Table 1 summarizes the fraction of families and species killed in each of the big five mass extinctions. In fact, the fraction of species killed cannot be measured directly from the fossil record since the preservation of individual species is too unreliable; the majority of species appear in only one stratigraphic stage so that no statistically significant estimate of their origination or extinction time can be made. The fraction of families killed can be calculated with reasonable certainty: Many families have reasonable coverage in the fossil record so that good estimates can be made of origination and extinction times. Estimates of species kill are then extrapolated from the family-level estimates by a technique known as reverse

Table 1 Extinction intensities at the family and species level for the big five mass extinctions of the Phanerozoic^a

Extinction	Family loss (observed) (%)	Species loss (estimated) (%)
End Ordovician	26	84
Late Devonian	22	79
Late Permian	51	95
End Triassic	22	79
End Cretaceous	16	70

^aEstimates of family extinction are obtained from directed analysis of the fossil record, whereas species loss is inferred using a statistical technique called “reverse rarefaction.”

Source: Reproduced from Jablonski D (1995) Extinctions in the fossil record. In: Lawton JH and May RM (eds.) *Extinction Rates*. Oxford: Oxford Univ. Press.

rarefaction which works as follows. First, one denotes the probability of extinction of a particular species within a family as p . If the family contains only one species, then p is also the probability of extinction of the family. If it contains two species, however, then the probability of extinction of the family is p^2 . In general, if the family contains n species, then the probability of its extinction is p^n . Then one averages this over many families to find the average probability of extinction of a family. In order to perform the average, we need to know the distribution of the sizes of families. Following Raup (1979), data from living species are usually used for this purpose. Calculating the average probability of family kill gives us a “rarefaction curve” (Figure 3) for the fraction of families or genera killed as a function of the fraction of species killed. “Reverse rarefaction” is the name given to the use of this curve “backwards” to estimate what fraction of species must have been killed in order to produce an observed level of family kill. This is the method which is used to calculate the data in Table 1.

Another overall feature of the extinction record shown in Figure 2 is a decline in the level of background extinction (i.e., not mass extinction) during the Phanerozoic. Like the increase in standing diversity discussed earlier, it is important to establish whether this decline is a real effect or the result of some bias in the record. It is difficult to imagine that a decrease in the number of families becoming extinct could arise from better preservation toward the Recent. Rather, one would expect the reverse since, if extinction were actually approximately constant but more fossil families were preserved, one would expect an increase in apparent extinction. What is the explanation for the decrease? Many hypotheses have been put forward.

Flessa and Jablonski (1985) suggested that the decrease could be a result of increases in the average number of species per family toward the Recent. If families increase in size (as seems to have been the case), then the probability of extinction, which was denoted as p^n , will decrease as n , the number of component species, becomes larger. A related suggestion has been made by Boyajian (1986), who proposed that families “age” over time, meaning that they accumulate more species (on average) the longer they live and therefore become resistant to extinction. If the number of such aged families increased over time, this could explain the decrease in extinction rates. This explanation receives some support from the fossil record, which indicates that families have indeed

Figure 3 Rarefaction curves for the extinction of families (solid line) and genera (dashed line) calculated for echinoderms by Raup (1979). The curves indicate what percentage of families or genera are expected to become extinct during an event which kills a given percentage of species. Used in reverse, the curves also allow us to estimate what percentage of species became extinct in a particular event, given an observed percentage of family or genus kill.

tended to live longer in recent times than they did in the early Phanerozoic. The average lifetime of a family in the Paleozoic is estimated to be about 30 million years but increases to about 80 million years in the post-Paleozoic.

Gilinsky and Bambach (1987) and Gilinsky (1994) made a slightly different argument that the decrease is a “taxon sorting” effect. Suppose that taxa (e.g., families) vary in volatility. That is, the species within some of them undergo comparatively rapid speciation and extinction and turnover is high, whereas the species within others speciate and die out relatively slowly. For the highly volatile families, the time to extinction of the entire family, as a result of extinction of all its members, will be shorter than that for less volatile ones by precisely the ratio of the respective volatilities, meaning that the highly volatile families become extinct more quickly. Over the course of a long period of time, therefore, the families that remain will tend to be the less volatile, longer lived ones. Taxon sorting in effect produces a selection pressure at the family or other higher taxonomic level. Another possible explanation for the increase in the lifetimes of taxa and decrease in extinction rates is that species have really become more highly evolved toward the Recent and are better adapted to survive (Raup and Sepkoski, 1982). This explanation, however, is not a widely accepted one.

Although extinction has received the lion’s share of paleontological attention in recent years, origination is equally important in the study of Phanerozoic biodiversity. We have already discussed origination in the context of the “three faunas” view of the diversification of life. Figure 4 shows a detailed plot of the measured pattern of origination of families during the Phanerozoic. Many prominent features are visible. The major peaks in the Cambrian period are a reflection of the burst in metazoan diversity of the Cambrian explosion. Since the plot is one of origination rates as a fraction of standing diversity, however, the size of these peaks is partly just a result

Figure 4 Estimated origination of marine animals in families per stratigraphic stage since the Cambrian as a percentage of the total number of families in existence.

of low Cambrian diversity (Figure 1). Another burst of origination is visible in the Ordovician. This burst was responsible for the corresponding major increase in diversity shown in Figure 1. After the Ordovician, origination is more subdued, although substantial surges did take place in the Triassic, Jurassic, Cretaceous, and during the Cenozoic.

On the whole, origination tends to vary less in magnitude and to be less episodic than extinction (Foote, 1994). Nonetheless, it appears to be bursts of origination, rather than declines in extinction rates, which account for most of the major evolutionary radiations. The basic features of the Ordovician, Jurassic–Cretaceous, and Cenozoic radiations are as follows.

Origination during the Ordovician occurred particularly among groups such as brachiopods, bryozoans, and mollusks, increasing the dominance of these groups while groups such as trilobites shrank in importance. Although phyla had basically ceased to be produced by the Ordovician, the period led to substantial production of body plans at the level of classes and orders.

The Jurassic–Cretaceous radiation produced substantial increases in the diversity of gastropods, bivalves, echinoids, and fishes—groups that were relatively minor during the Paleozoic. Ecological expansion in the form of the appearance of fundamentally new modes of life (Bambach, 1985) and the increasing occurrence of predation (Vermeij, 1977) have been advanced as important contributors to this pattern.

The Cenozoic radiation is certainly in part a product of the Pull of the Recent, but there are also genuine bursts of origination in the Paleocene and Eocene. In the marine realm, the diversity of veneroid bivalves, neogastropods, irregular echinoids, gymnolaemate bryozoans, and fishes increased substantially, whereas in the terrestrial realm the mammal and angiosperm radiations are particularly prominent.

Although mass extinctions are usually explained as the results of various kinds of exogenous stress on the ecosystem, such as climate change or bolide impact, originations seem to be more often the result of biological phenomena such as evolutionary innovations or changes in the structure of

ecological assemblages. However, as a close inspection of Figures 1, 2, and 4 reveals, origination is often intensified in the aftermath of mass extinction events, suggesting that physical disturbances do have an indirect effect on origination, probably through removal of incumbent species, through selectivity in extinction (Jablonski, 1989), and through particular patterns of rediversification of groups and repopulation of ecospace during the recovery period following extinction. Recoveries typically take a few million years to run their course and reestablish previous levels of diversity and ecological heterogeneity (Erwin, 1998). Some recoveries do not begin immediately after an extinction event; there is a lag, perhaps as long as a few million years, probably the result of lingering environmental stresses and the proliferation of opportunistic species. A paradigmatic example of recovery is the Triassic recovery which followed the end Permian (Figure 4). A conspicuous spike in origination is observed beginning about 5 million years after the end of the extinction and continuing for about another 5 million years.

A long-term decline in origination over the Phanerozoic is as clear a feature of the fossil record as is the decline in extinction. Taxon sorting of the kind described earlier in the context of extinction is a plausible explanation (Gilinsky, 1994). Alternatively, the decline in origination may reflect a genuine decrease in the rate of evolutionary innovation as a result of either ecological or developmental restriction (Gilinsky and Bambach, 1987; Eble, 1999).

It is also instructive to examine origination rates at the level of higher taxa such as classes and orders. Origination at these levels reflects real innovations (to the extent that they are visible in the fossil record) rather than just sheer numbers of species. Indeed, there is no reason why the two need necessarily be correlated. During the Cambrian, for example, changes in total diversity (e.g., measured by the number of families) are modest, but it is in the Cambrian that one finds the most significant generation of new body plans—the “Cambrian explosion.” This aspect of biodiversity having to do not with numbers of evolving entities but with their distinction is often referred to as “morphological diversity,” “biodisparity,” or simply “disparity” (Foote, 1997). Significant discrepancies between biodiversity and biodisparity can exist, such as faster morphological diversification early on in the evolution of clades, despite low levels of taxonomic diversity, and later deceleration despite continued increases in diversity. Further understanding of biodiversity in the fossil record may hinge on a better understanding of such patterns.

Glossary

Efficiency The degree of success in reaching a conservation goal relative to the cost (or to some surrogate for cost, such as number of areas). For goals such as maximizing the number of species represented for a particular cost, a distinction should be made between merely selecting areas on the basis of any records of species and choosing areas that maximize persistence of species in the long term.

Flexibility The degree to which alternatives exist for one or more selected areas in the context of reaching a particular conservation goal. When seeking a set of areas to represent maximum diversity, flexibility for a selected area may be absent, incomplete (replacing the selected area while still reaching the conservation goal would require substitution of two or more areas, or one or more areas of greater cost), or complete (other areas could be substituted, one-for-one by number or by cost, with the current choice).

Goals An explicit and precise statement of conservation aims. Goals should express the values of those people who provide the mandate for conservation. Making the goal explicit allows efficiency to be measured as an aid to accountability. A statement should include which attributes are valued (such as genetic diversity), which surrogates for this value are actually surveyed (such as higher taxa, species, and threatened species), which areas are to be considered

(such as land management units or grid cells), and how constraints of viability, threat, and cost are to be measured and accommodated. Goals are not universal, but depend on people's values and their situations. Consequently, different goals may conflict, and areas necessary to meet one goal may be insufficient to meet broader goals.

Irreplaceability A property of areas that include species (or other valued attributes) restricted to so few areas that all such areas would be needed to meet a conservation goal.

Priority areas Areas that need the most urgent management, e.g., action to avert threat to meet a conservation goal (such as to increase the probability of persistence of valued species or other attributes). Ranking of areas by priority may differ from their ranking by value.

Representation The occurrence of species (or other attributes) within a set of selected areas. A distinction must be made between records of a species and areas with high probability of persistence for the species in the long term.

Values Values are interpreted here in the broadest sense, to include monetary and nonmonetary values. Biodiversity attracts many different values, which are not universal, and which depend on social and economic situations. Consequently different values may conflict.

Origins: The Biological Basis of Complementarity

Figure 1 shows a simple example of species complementarity for the mammal faunas of two areas. These faunas share one species, the lion, but each fauna also has species that are not shared. It is the species in one fauna that are not shared with a second fauna which are said to be "complementary" in relation to the second fauna.

The biological causes of complementarity are the processes that lead to differences among biotas. Fundamentally, the causes are descent with modifications, leading to differences among genes, species, and biotas. At the species level, the processes affecting this are familiar from differences in ecology and history. In ecology, differences among species in their responses to the environment, including responses to other species, lead to differences in species distributions near equilibrium. Unique events in history, particularly the gain or loss of barriers that prevent any approach to equilibrium with governing ecological factors,

Figure 1 Complementarity. The two ellipses represent two areas, one with a fauna of two and the other with a fauna of three mammal species. They share one species, the lion. The zebra and giraffe in the lower area are complementary to the fauna of the upper area, whereas the antelope of the upper area is complementary to the fauna of the lower area.

also contribute to species distributions, as studied in vicariance biogeography.

The description of patterns of complementarity at the species level is closely related to the description of spatial turnover, also known as beta or gamma diversity, depending on the spatial scale being studied. Similarly, patterns of complementarity in biodiversity may be expected to be highly dependent on spatial scale. This is because the size of area patches used to study patterns in the distribution of species has a strong effect on measures of their co-occupancy of these patches.

Importance for Cost-Effective Biodiversity Conservation

Need for Complementarity in Area Selection

Complementarity is an apparently simple idea that has considerable power to aid area-selection methods for conserving as much biodiversity as possible. While decisions on area selection will always benefit from experienced judgment, quantitative methods provide a framework of rules designed to make such complex decisions more rigorous and efficient, and more open to public accountability (Margules and Pressey, 2000). Complementarity value is a particular case of the idea in land-use planning of “marginal value,” which is the incremental gain accrued when the area is managed in a particular way as part of a land management plan.

Accountability is important because conservationists should be acting in the broader interests of society, so people ought to be able to see that their values are being acted upon, and that limited resources are not being wasted. Accountability makes it possible to trace precisely why one area is chosen in preference to another, and if necessary, to challenge the data or rules.

Efficiency is important because the area of land (or volume of sea and air) available for conservation is limited, as there is often competition between conservation and other incompatible land uses. Efficiency ought to be considered in relation to the goal of ensuring effective long-term persistence of biodiversity.

	Species								
	a	b	c	d	e	f	g	h	
1	.	.	X	X	X	X	X	.	Hotspot richness
2	X	X	X	X	.	.	.	.	Minimum complementary set
3	.	.	.	.	X	X	X	X	
4	X	X	X	.	.	.	.	.	
5	.	.	.	.	.	X	X	X	

Figure 2 Hotspots and complementarity. Five areas have a biota of eight species. Area 1 is the hotspot of highest species richness (five species). However, this area is not part of the minimum fully representative set for all eight species, which is the combination of areas 2 and 3.

As an example of the efficiency and accountability that comes from using complementarity in area selection, suppose we could choose only two areas from **Figure 2** to represent as much biodiversity as possible, it might be tempting to begin by choosing area 1, the “hotspot,” because it has the largest number of species (five). The next richest area would be area 2. Areas 1 and 2 would then represent a total of seven species (a–g). However, we can see from **Figure 2** that areas 2 and 3 have completely different (highly complementary) biotas, so if chosen together, these two areas alone could succeed in representing all eight species (a–h).

History of Complementarity in Area Selection

Complementarity-based methods were first described by Kirkpatrick (1983). The term “complementarity” was coined specifically in the context of area selection by Vane-Wright *et al.* (1991). The importance of the term is that it identifies a property essential to a group of techniques that have proven to be more efficient (Pressey and Nicholls, 1989).

The impetus for the development of complementarity methods in conservation has been strengthened in the last 10 years by Agenda 21 and by the Biodiversity Convention. These policy initiatives gave a new emphasis to conserving the value of broader biodiversity, in addition to the long-recognized need to conserve the relatively few, particularly threatened or vulnerable species. Conserving broader biodiversity presented several new challenges, particularly in keeping track of the very large numbers of components of which biodiversity is comprised.

Complementarity-based methods have been used more in the Southern Hemisphere (particularly in Australia and South Africa), where knowledge of the biota comes more often from new surveys, some designed specifically for identifying potential conservation areas. In contrast, complementarity methods have been less popular in countries with a long natural history tradition and with a strong local knowledge base, where many locally important areas may already be well known (although rigorous prioritizing among them or adding to them efficiently may still be difficult without using complementarity). Nonetheless, there is a growing interest in complementarity methods by the US Gap Analysis Program, The Nature Conservancy, Conservation International, and by biological recording schemes in Europe.

Application to Simple Species Representation

Setting Goals

A common goal of biodiversity conservation projects is to ensure the persistence of as much biodiversity as possible for the future. The basic form of the problem is one of optimizing the number of valued components of biodiversity (usually species) represented within a set of areas (whether these are to be protected or not), subject to constraints including species viability, threat, and cost.

A simple representation goal used to illustrate the basic principles in many academic studies has been to achieve at least one representation of every included species within the

reserve network. Alternatively, the goal could be to achieve any required number of representations (this number could also differ among species), or could be expressed in terms of population size, or probability of occurrence. For many studies to date, information on constraints has been less-widely quantified (although perhaps because less effort has been invested). Viability and threat are often either ignored or are treated only by using crude rules.

In the simplest formulation of conservation goals, the cost constraint on area selection can be represented by the number of areas, treating all areas as being of equal cost. A few studies have used the extent of areas of differing size as a measure of cost. Even when financial cost data have been used, they have rarely included a thorough consideration of all the appropriate cost components. These may include cost of area acquisition, costs of management to reduce threats, the number of people impacted if the area should be set aside for conservation, and (crucially) the opportunity costs that arise from income from any alternative uses of an area (e.g., forestry and agriculture) that is foregone when it is managed for biodiversity conservation (Faith and Walker, 1996c).

An important part of specifying an area-selection goal must be to include the contribution of an existing conservation network. If some species can be considered to be adequately protected by the existing network, then only the complementary species need be targeted for additional representation. This is the idea behind “gap analysis,” which is essentially about finding the complement to the existing coverage.

One kind of goal (the minimum-cost problem) is of the form: “which is the minimum set of areas required to represent the diversity of species?” to achieve at least one representation (or any other required number) for species within the area set. Another kind of goal (the maximum-coverage problem) takes the form: “how can we choose 1% of the total area to represent the greatest diversity of species?”

Complementarity-Based Techniques

Achieving the representation goals described in the previous section is not entirely straightforward. For example, the size of the problem when seeking a minimum-cost set of areas cannot be calculated simply from the numbers of species and areas (this kind of problem is described as not-polynomial complete or “n-p complete”).

Fortunately, the problem is familiar for many kinds of similar applications in Operations Research, where a range of techniques for dealing with it have gained acceptance. First, exhaustive search can test every possible combination of areas to find the optimum, although this is usually prohibitively slow. Second, branch-and-bound algorithms can restrict the search to only a subset of all possible combinations of areas, but a subset within which the optimal solution is expected to lie. They have become a more practical option, but may be slow, may require specialist software, and may not be able to solve all problems (Pressey *et al.*, 1996). Third, heuristic algorithms can use relatively simple sets of rules that have been found from the experience with previous datasets, to give good approximations to optimal solutions. In practice, heuristic suboptimality may be trivial compared with concerns about

data quality and practical implementation for conservation (Pressey *et al.*, 1996). Heuristics are also easy for non-specialists to implement, with or without computers.

Flexibility, Priority, and Irreplaceability

Quantitative area-selection techniques frequently identify several alternative combinations of areas that meet their representation goals. This allows for flexibility in the final area choices (Pressey *et al.*, 1993). In general, more constraints placed upon the optimization problem mean less flexibility in the solution. When using exhaustive or branch-and-bound area-selection techniques, flexibility may be identified directly as alternative optimal sets. When using heuristic techniques, however, it is done indirectly, by identifying which species each selected area contributes uniquely to the representative set. Any other area that shares these same “goal-essential” species (Rebello, 1994) could be substituted in its place, and is therefore a fully flexible alternative.

Priority is regarded here as the urgency with which areas require management action for conservation to avert threats to the persistence of their biodiversity value. Therefore, priority ranking of areas may differ from their ranking by biodiversity value or by their flexibility. The distinction between value and priority is important but often ignored.

Areas within a representative set for which there are no flexible alternatives (to meet a particular goal) have been described as “irreplaceable,” an all or nothing property. However, “shades of irreplaceability” has also been used to refer to the relative number of alternatives that may exist for an area choice, depending on how widespread the species occurring there may be (Pressey *et al.*, 1994). Shades of irreplaceability concerns the frequency with which an area is required among all possible fully representative area sets, whatever the size or cost of the set. This frequency usually depends on the rarest species in each area, because a rare species has few alternative areas available to represent it. Using the definitions at the beginning of this article, shades of irreplaceability is a measure of flexibility rather than a measure of the conservation value of an area (which might be measured in terms of its complementary biodiversity value).

Assessing Efficiency

Much of the emphasis on using complementarity in area selection is on how it can be used to represent more biodiversity with limited resources. The relationship between representation and cost has been identified with concepts of efficiency. However, efficiency ought to be considered in relation to not just representation of species records, but in the context of all the other constraints (viability, threat, etc.) necessary to reach the goal of ensuring the effective long-term persistence of biodiversity.

For minimum-set goals, the efficiency of species representation was measured by Pressey and Nicholls (1989) as the proportion of all areas that is “not” required to meet the goal. This is an absolute measure, in the sense that efficiency is judged relative to selecting all areas or none.

Because the absolute efficiency that can be achieved in any particular case varies with patterns in the data, it may be more useful to measure efficiency relative to what might actually be expected with those particular data. In the past, efficiency of species representation has often been assessed informally by comparing species-accumulation curves for ordered sequences of selected areas. The upper bound to this is the maximum representation within the chosen constraints, the maximum-coverage set ($s_{\max,c}$) for the given constraints (c). Some studies have also used simulated random draws of areas (without replacement), to estimate whether the representation achieved by an area set is significantly greater than would be expected by chance, when selecting the same number

of areas (Figure 3a, c). One useful lower bound for comparison is the representation that might be expected if areas were selected at random ($s_{\text{rand},c}$), without regard to their biota. Therefore, for the representation within an observed set of areas ($s_{\text{obs},c}$) for the same constraints, the relative efficiency of any set of areas ($E_{\text{obs},c}$) for constraints c is given by

$$E_{\text{obs},c} = (s_{\text{obs},c} - s_{\text{rand},c}) / (s_{\max,c} - s_{\text{rand},c})$$

In the simplest form of this measure, the number of areas can be used as a measure of the cost constraint, in which case efficiency is measured relative to what might be expected from the data when selecting a particular number of areas (Figure 3b, d).

Figure 3 Species representation and relative efficiency. (a) Cumulative percentage of a group of 426 species of Oregon vertebrates represented within increasing numbers of hexagonal grid cells (each 635 km², as developed for the Oregon Gap Analysis Program) selected using maximum-coverage (branch-and-bound algorithm), near-maximum coverage (heuristic algorithm), hotspots of richness, and hotspots of rarity (richness in the rare-quartile of species), and areas chosen at random. Scores above the solid gray line (the percentage threshold score to the top 5% within 1000 randomly drawn scores) are significantly better than expected when choosing areas at random. Data reanalyzed from Csuti *et al.* (1997). (b) Cumulative percentage of a group of 321 species of Madagascan butterflies represented within increasing numbers of quarter-degree grid cells (each ~170 km²) selected using near-maximum coverage (heuristic algorithm), hotspots of richness, and hotspots of rarity (richness in the rare-quartile of species), and among areas chosen at random. (c) Results from (a), rescaled for relative efficiency between the maximum that can be achieved (using the branch-and-bound algorithm), and the median representation expected from selecting areas at random (relative representation efficiency: $E_{\text{obs},n} = 100(s_{\text{obs},n} - s_{\text{rand},n}) / (s_{\max,n} - s_{\text{rand},n})$). Scores above the solid gray line are significantly better than expected when choosing areas at random. Data courtesy of David Lees. (d) Results from (b), rescaled for relative efficiency between an approximate estimate of the maximum coverage that can be achieved (using a heuristic algorithm), and the median representation expected from selecting areas at random. Because the heuristic algorithm is likely to be further from the optimum when very small numbers of areas are selected, the corresponding estimates of relative efficiency may be less reliable.

The maximum absolute efficiency in species representation that can be achieved using complementarity is determined by patterns in the data of co-occupancy of areas by species (i.e., “nestedness”). For example, if all species were found in one area, then only one area would be needed as a minimum to represent them; whereas if none of the species were found together, then as many areas as species would be needed (Vane-Wright *et al.*, 1991).

Application to More Complex Problems

Complementarity and Probability of Persistence or Occurrence

Ultimately, effective biodiversity conservation is about ensuring the long-term persistence of valued biodiversity. One way to improve area selection is to estimate the probability of persistence of species in different areas.

Probabilities of occurrence can be estimated by fitting explanatory models to distribution data. A popular approach is to use niche-based models, which assume a unimodal response by species to variation in environmental variables, such as climate. Probabilities of occurrence are sometimes also used alone to overcome the problem of incomplete species occurrence data, without attempting to adjust for viability and threat.

The simplest approach to treating viability in area selection is to include only those populations that are considered to be viable. Unfortunately, the data required to decide this are rarely available. To deal with threat, areas where species are known to be under severe threat might be excluded from consideration because they are deemed to be irretrievable. Alternatively, the cost of averting threats might be included in the area cost.

At least in principle, probabilities of occurrence (at the time when data were obtained) could be converted to estimated probabilities of persistence (the probability of continued occurrence at some specified time in the future) if threats and species’ responses to those threats could be predicted. There are usually substantial uncertainties associated with this process. Alternatively, if it can be assumed that conservation management can ameliorate all threats in any selected areas, then probabilities of persistence can be expected to be related positively to probabilities of occurrence. Either way, techniques are available to seek complementary areas to reach a conservation goal that is expressed in terms of probabilities with efficiency (Williams and Araujo, 2000).

Complementarity and Changing Distributions

The effect of any anthropogenic environmental change on distributions can be estimated using niche-based models of

Figure 4 Assessing indicators of complementarity. Scatter frequency plot of complementarity scores for a sample of 2776 pair-wise comparisons drawn at random from among 2776 British 10 × 10 km grid cells with presence data for both selected birds (105 species) as indicators of vascular plants (1353 species). Higher frequencies of scores are shown by larger circles. Medians on each axis are shown by solid lines. Quartiles are shown by dashed lines, defining opposing quartile boxes, with points within these boxes shown as diamonds. Reproduced from Williams PH, Faith D, Manne L, Sechrest W, and Preston C (2006) Complementarity analysis: Mapping the performance of surrogates for biodiversity. *Biol. Conserv.* 128: 253–264.

habitat suitability, for example by fitting habitat models across a series of time slices using the expected changes in predictive environmental variables. These equilibrium models of habitat suitability need to be combined with species dispersal models to constrain species expected distributions to those areas that species are likely to be able to reach by dispersal. Some species may have to disperse if they are to persist at all. Consequently, conservationists are interested in the potential to identify corridors or stepping stones to aid dispersal of these species. Efficiency has required techniques that seek complementarity in the selection of chains of areas rather than among single static sites (Williams *et al.*, 2005). Further developments in this area can be anticipated.

Finding Indicators of Complementarity within Broader Biodiversity

Data are rarely available for all of the valued parts of biodiversity. One attempt to deal with this problem is to use data for one group of (related or unrelated) species as a surrogate or indicator for another group (Ryti, 1992), or ideally for all of biodiversity. The success of this approach relies on the congruence in distributions between the indicator and indicated groups, not just in patterns of richness, but also in patterns of complementarity at different spatial scales. Reliable indicators

of complementarity have proven difficult to find, with some indicators resulting in no more species being represented than when areas were chosen at random. Unfortunately, many attempts to assess the value of indicators as predictors of complementarity within biodiversity have substantial flaws or limitations.

First, some authors have claimed that complementarity is a kind of dissimilarity, and have used symmetrical dissimilarity metrics, particularly Bray-Curtis, as a measure of complementarity. This approach is seriously flawed, because complementarity between pairs of biotas is usually asymmetrical, and may be strongly so. For example, a small coastal island may have only a small subset of the biota of the neighboring mainland, without additional species. In this case, the mainland has high complementarity with respect to the island, but the island has no complementarity with respect to the mainland. Another common weakness of this first approach is that using the mean (or median) value for a complementarity measure to assess prediction between groups could be misleading. For example, Figure 4 shows a scatter plot of complementarity scores (numbers of complementary species of birds, x , and plants, y) for pairs of areas. If Figure 4 had similar ranges of values on both axes, and if the complementarity values were concentrated both near the origin and in the upper left and lower right corners, but not in the middle, then

Figure 5 Flexibility and representation of other species. Histograms of representation of all mammals and breeding birds within flexible sets of 50 one-degree grid cells (each $\sim 11,025 \text{ km}^2$) in sub-Saharan Africa, each selected for maximum coverage of three different groups of species: (upper) six flagship mammals; (middle) five orders of larger mammals; and (lower) all mammals and breeding birds. With the exception of the histogram at the bottom, which shows all 120 flexible sets of 50 cells, scores are from a randomly drawn sample of 1000 alternative sets from totals of 2.12×10^{86} flexible sets of 50 cells for flagship species and 6.54×10^{41} flexible sets of 50 cells for larger mammals. Representation scores to the left of the dotted line are within the range expected when choosing 50 grid cells at random. Redrawn from Williams PH, Burgess ND, and Rahbek C (2000) Flagship species, ecological complementarity, and conserving the diversity of mammals and birds in sub-Saharan Africa. *Anim. Conserv.* 3: 249–260.

mean (or median) complementarity for the two groups could be very similar, even though true prediction of complementarity would be very poor (with most predictions being falsely high or falsely low).

A second approach has been to apply complementarity-based area selection to both an indicator and the group to be predicted, and then examine the spatial overlap between the two area sets. This approach is flawed because only one of a large number of alternative flexible area sets is considered in each case, which may be unrepresentative of the entire population of sets, and it says nothing about whether or not areas within the subset of overlapping areas include most of the complementarity, or make only minor contributions. It is possible for the complementary contribution of an overlap area to differ strongly between the predictor and predicted groups of organisms.

The third and more common approach recently has been to apply complementarity-based area selection using an indicator and then sum the representation of another group within the area set. In Figure 5, all the 120 flexible sets of 50 areas selected for maximum coverage of all mammals and birds must by definition have the same number of mammals

and birds. However, when sets of 50 areas are selected for maximum coverage of just the flagship species, or just the large mammals, then any flexible sets may vary in the numbers of all mammals and birds represented. This approach, although a good start, has limited value because whether the results include only one area set, a large sample of flexible sets (Figure 5), or even all area sets, they do not include the pattern of complementarity among all areas.

To assess the indicators for broader biodiversity more broadly, we need methods for assessing whether they are good predictors of complementarity across all areas (Williams *et al.*, 2006). The fundamental measure (Figure 4) is the complementary richness of a “focal biota” for one area with respect to a “reference biota” of other area(s) (which might be under some form of conservation management, referred to here for convenience as a “reserve”). This complementarity measure is then plotted for the indicator or predictor on the *x*-axis, against the corresponding complementarity for the same area comparison but for overall biodiversity on the *y*-axis. The reference biota in this comparison can be contributed by any number of areas: from 0 (whereupon the calculation simplifies to one of species richness) to a single area, to a set of areas,

Figure 6 Declining predictivity of complementarity as reserves are selected. Frequency plot of complementarity scores for a sample of 2776 comparisons drawn at random from among 2776 British 10×10 km grid cells with presence data for both birds (105 species) as indicators of vascular plants (1353 species). In each case, one focal cell is compared with a group of reference cells drawn at random: (a) 0 reference cells; (b) 1 reference cell; (c) 4 reference cells; and (d) 16 reference cells. Reproduced from Williams PH, Faith D, Manne L, Sechrest W, and Preston C (2006) Complementarity analysis: Mapping the performance of surrogates for biodiversity. *Biol. Conserv.* 128: 253–264.

and up to the total of all other areas with records (whereupon the calculation simplifies to one of “endemism” at the scale of the analysis). Because when dealing with large numbers of grid cells the number of comparisons can become very large, the focal area and a single reference area can both be selected at random to make a sample of comparisons (Figure 4). To address the problem of interdependence among pair-wise data points, segments of the frequency distribution can be compared. The number of points falling within the opposing upper and lower quartiles on the plot (dotted lines in Figure 4), which correspond to false high and false low predictions are counted. To test for significant predictivity of complementarity by possible indicators, the numbers of these departures from a predictive relationship must be significantly lower than would be expected from a null model, which is used to reassign local biotas at random.

Indicator relationships change as the number of reference “reserve” cells increases. Initially, when there are no reference cells, the scores for each focal cell are simply the species richness scores for those cells. When there is one reference cell, then the scores for the focal cell are complementary with respect to that single cell. As the number of reference cells (which could be the number of cells in an existing reserve network) goes up, the score for the focal cell becomes increasingly dependent on some of the most narrowly distributed species in the data. There is a corresponding increase in

the scatter of the predictive relationship (Figure 6), so that the strength of the predictive relationship decreases with an increasing percentage of false predictions. However, the predictivity of complementarity can remain significant.

The spatial pattern in false predictions can also be mapped. Areas on these maps associated with many false high predictions are overvalued and would be an inefficient investment for scarce conservation resources. Areas associated with many false low predictions are undervalued and unlikely to attract conservation action, so we need to know whether they are particularly likely to be highly threatened. Any geographical patterns could be used to identify habitat-associated biases in the performance of indicator groups.

Patterns of complementarity might be expected to differ among groups of organisms because they differ in the ecological and historical processes that have shaped their distributions. For example, some groups share closer ecological similarities in diet, habitat, and climatic tolerances. If some of them have diversified at the same time and in the same areas, they may also have shared similar phylogenetic and biogeographic patterns, as envisaged by vicariance biogeography. When seeking groups of species to use as indicators for use in area selection to represent other groups or broader biodiversity, what will be needed is shared patterns of complementarity within ecological or phylogenetic patterns.

Figure 7 Improving indicators of complementarity by selecting species with particular range properties. The gray bars are results from trial “indicator” groups of 155 species constructed at random and used to choose a set of 24 areas: the height of the bars shows the relative frequency and the x-axis shows the number of nonindicator species represented (from among 2937 remaining species) in each area set selected using the randomly selected “indicator” groups. At the far left of the x-axis is the upper 5% threshold of significance for species representation from choosing 24 areas at random. At the far right is the best 24-area set possible from using all 3092 species to make the area selection. The black bars show the improvement in species representation above the gray bars when groups of 155 indicator species are chosen using (i) species with low variance in geographic ranges among ecoregions; (ii) species with low mean range sizes; (iii) species showing low mean species richness (among grid cells containing indicator species); and (iv) a high proportion of plants or restricted plants (which tended among the species examined to have smaller range sizes). Reprinted from Manne LL and Williams PH (2003) Building indicator groups based on species characteristics can improve conservation planning. *Anim. Conserv.* 6: 291–297.

Can groups of species be chosen to improve their performance as indicators of complementarity in biodiversity? Manne and Williams (2003) showed that even indicator groups comprising of randomly chosen, taxonomically unrelated species performed better than randomly chosen areas. Furthermore, they demonstrated that area-selection performance could be improved when using groups of indicator species that had been chosen on the basis of the characteristics they found to be associated with good indicators (Figure 7).

Pattern Complementarity

Complementarity, as well as being applicable to discrete entities such as species, can also be applied to patterns that might be used to predict their distributions (Faith and Walker, 1996b). This extension of the indicator idea has been applied in two areas.

First, complementarity has been used in seeking sets of genotypes (usually species) to represent genetic diversity efficiently (Vane-Wright *et al.*, 1991). In this case, phylogenetic trees are seen as patterns that can be used to predict genetic differences between terminal genotypes (species), because the genes are expected to follow a hierarchical model of descent with modification along the branches of the tree (Williams *et al.*, 1995). This led to the development of a subtree-length measure of phylogenetic diversity (or PD) (Faith, 1994), which is widely accepted.

Second, complementarity has been used in seeking sets of areas to represent ecological diversity (ED) efficiently. The pattern used is the evenness with which species or areas are distributed within a multivariate ordination space of environmental variables. The unimodal response model for how each species' ecological niche occupies a part of this environmental space means that this pattern of species' distributions within the space can be used to predict their occupancy of candidate areas for selection. Consequently, particularly in cases of incomplete species distribution information, this approach may represent ED with greater efficiency (Faith and Walker, 1996a). This approach holds the promise of being able to predict complementarity within broader biodiversity, but in practice it is weakened by the strong departures of many real species distributions from the assumption of equilibrium with their ecological governing factors. Many aspects of the approach remain to be explored.

Conclusions

Using complementarity in area selection for biodiversity conservation is not only accountable and efficient, but also can be much more flexible for dealing with diverse and heterogeneous goals and data than simple exercises may imply. Complementarity can be applied in combination with any available and appropriate information on the distribution of diversity: on its viability, on threats, on costs, on its distribution within multidimensional environmental space, and on any other ecological or social constraints that are currently being used to make decisions. Consequently, it should be widely applicable with even very complex data to improve

upon *ad hoc* decisions. The major challenges for the immediate future are how best to predict probability of persistence and threat from limited information and how best to integrate this information into complementarity-based area-selection methods.

Glossary

Biota Fauna and flora; the organisms in a given place.

Coevolution Evolution where two species have a mutual influence on each other.

Genetic drift Change in gene frequencies due to random fluctuations in a finite population.

Heterostyly Having two or more kinds of flowers with stamens and pistils of different lengths.

Mimicry Defensive mechanism in which organisms of two species resemble each other, ordinarily because at least one of them is distasteful.

Morphology The study of form.

Phylogeny The history of a species or lineage.

Pleiotropy Phenomenon of a gene affecting more than one trait.

Sexual selection Kind of selection that Darwin distinguished from natural and artificial selection in which reproductive success depends on monopolizing mates.

Taxon Group of organisms in a formal system of classification.

Introduction

Although natural selection theory is generally considered as Darwin's most important and original contribution to knowledge, he also deserves the credit for providing compelling evidence that evolution is a fact and for making its fundamental implications clear. Indeed, Darwin began an intellectual revolution of the first magnitude, one that has affected the whole scope of modern life and culture. Indeed it is still going on. The emphasis here will be on those aspects of Darwin's contribution and of Darwinism in general that are particularly relevant to the study of biodiversity. Within biology it has been the sciences of systematics and ecology that have been most revolutionized by Darwinian thinking because it enables us to understand both how and why diversity originates and is maintained. Some of the larger philosophical and social issues will also be considered, especially as they relate to the central theme. These include the rejection of teleology, the replacement of typological thinking with population thinking, the recognition of the importance of historical contingency, and a competitive view of the natural economy.

Darwin's Life and Work

Childhood and Education

Charles Darwin was born on February 12, 1809, in Shrewsbury, England. His father was a wealthy physician and his mother was a member of the Wedgwood family, famous for

the manufacture of pottery. She died when he was eight years old. Young Darwin was not very successful in school and at the age of sixteen he was sent to study medicine at Edinburgh University. There he was able to cultivate his interest in natural history, largely on an extra-curricular basis. A decision to abandon medicine in favor of preparation for a career as a clergyman led him to enroll in Cambridge University on October 15, 1827. During the years at Cambridge he continued his largely extracurricular studies of natural history and received much encouragement from both faculty and students. In those days there was nothing unusual about a clergyman also being a scientist, a university professor, or both. Darwin attended the botany lectures and field trips arranged by Professor John Stevens Henslow (1796–1861) and became an enthusiastic collector of beetles. He passed the examinations for his BA degree on January 22, 1831 but remained there to complete his residency requirements. He took up the study of geology and the following summer he obtained some field experience in the company of Professor Adam Sedgwick (1785–1873).

The *Beagle* Voyage

On September 1, 1831, Darwin accepted an invitation to join a surveying expedition on HMS *Beagle* as an unofficial naturalist and gentlemanly companion for the captain of the ship, Robert FitzRoy (1805–1865). The *Beagle* left for South America on December 27, 1831 and after sailing around the world finally got back to England on October 2, 1836. During the voyage, Darwin was able to observe and collect on a vast scale,

especially in South America, on the coasts of which most of the survey work was done. He also visited Australia, the Cape of Good Hope, and many islands along the way. At first his work emphasized the marine invertebrates that had interested him since his days at Edinburgh. But he took an increasing interest in geology. He read the first volume of the *Principles of Geology* by Charles Lyell (1797–1875) not long after the ship left port, and began to read the second volume the following November and the third in May of 1834. Darwin became an enthusiastic supporter of Lyell's uniformitarian methodology, and was also influenced by the discussions of biogeography and Lamarckism in the *Principles*. Darwin developed a theory of coral reef morphology while still working in South America. Later in the voyage he began to test it by means of observations on reefs. It was the coral reef theory, coupled with other geological work, that first established his high reputation as a scientist.

Observations during the voyage on the geographical distribution of animals and plants ultimately led Darwin to believe in evolution. The differences among geographically separated biotas and the peculiar character of insular ones were crucial in his thinking. It must be stressed, however, that these evolutionary insights did not happen instantaneously and that his commitment to evolution was a later development. Darwin began to take the possibility of evolution seriously only toward the end of the voyage, and the compelling evidence was not really in place until shortly after it was over, and some of his specimens had been examined by specialists. During his visit to the Galapagos Islands (from September 15 to October 20, 1835) he still assumed that species were immutable. He did, however, expect them to be somewhat adaptable, and to exist as local varieties. Some of the birds that he had supposed were just varieties turned out to be distinct species, implying that the inhabitants had diversified more than he had assumed was possible, and furthermore they had done it so locally. They were related by community of descent. This was just the beginning of many of his biogeographical insights. Facts such as the lack of frogs and other amphibians on islands far distant from land could easily be explained in terms of evolution, but otherwise remained a mystery. Contrary to the impression that one sometimes gets from text books, the most compelling evidence for evolution comes from biogeography, not the study of fossils.

Natural Selection

The fossils that Darwin collected in South America turned out to be recently extinct members of groups of animals that were still living in the same area. Again this suggested the possibility of local diversification. Around March, 1837, he began to search for an evolutionary mechanism. After much reading and theorizing, he discovered natural selection. This happened toward the end of September, 1838, when he read the *Essay on the Principle of Population* by Thomas Robert Malthus (1766–1834), who was among other things, a professor of economics. Darwin now understood how reproductive competition between organisms of the same species could produce evolutionary change.

The influence of Malthus on Darwin requires some elaboration here because it is so important for biodiversity studies. Malthus' ideas (or what have been represented as his ideas) have been controversial and have often entered into discussions on population planning and conservation policy. His basic point was that the growth of population tends to outstrip the growth of the food supply. His notion that the growth of population is exponential whereas that of the food supply is linear is well known, although it never was more than just a crude approximation. Malthus based his arguments on empirical evidence. After plagues and other catastrophes have reduced the numbers of human population there are fewer mouths to feed and the amount of food available per capita increases. Consequently people can and do support larger families and population grows rapidly. As time passes, the amount of food per capita decreases and population growth levels off, as people marry later and have smaller families. The standard of living tends to drop as well. A comparable situation could be observed where new land had been brought into cultivation, as in the United States, following which a high living standard was accompanied by rapid population growth.

Malthus saw a problem in this scenario with respect to the future economic prosperity of society: population growth would tend to depress the standard of living. There was a serious question in his mind, as well as those of his critics, whether his model of population growth need have those particular consequences. "Prudential constraints" (as he called sexual abstinence) would have some mitigating effect. The growth of technology has of course at least delayed the sort of famine that might be envisaged. However, the Malthusian model applies quite well to nonhuman populations. It contributed to Darwin's understanding of population dynamics, which he incorporated into his evolutionary and ecological theory. Darwin recognized that there was reproductive competition between individuals of the same species and because these individuals varied, those that were able to utilize resources more effectively would have more offspring. Natural selection follows when it is realized that the properties of those individuals that have more offspring are differentially transmitted by inheritance to the next generation. Extrapolating further, it made sense that natural selection would operate differently depending on whether or not population levels had been lowered by the effects of weather or other density-independent factors.

Given this kind of population dynamics, it became clear to Darwin that variation was far more important than had previously been understood. Natural selection would not work without it. This shift in emphasis is often discussed under the rubric of 'population thinking.' In contrast, the older 'typological' approach, which conceived of groups of organisms in terms of stereotypes, viewed the differences between individuals as a kind of departure from a norm, and these were screened out as unimportant. To the extent that variability had been recognized, it was assumed that something held it within definite limits. It was believed that species might vary but not so far as to give rise to new ones. At a deeper philosophical level, treating species as reproductive populations implied that they were very different from the 'natural kinds' of chemistry and other physical sciences. The new Darwinian thinking accepted that species were concrete, they had a

history, and they could evolve. Treating species as something more than abstractions was a major conceptual innovation.

The Long Delay

Following this shift in his thinking, Darwin immediately began elaborating a comprehensive theory of evolution together with its many implications. However, he was busy with other things and publication of his theory was long delayed. One factor in the delay was the decline of his health, which if not brought on by stress, was at least exacerbated by it. Ill health was a major consideration in his decision to leave London and live in the country. Darwin had married his cousin Emma Wedgwood on January 29, 1839, and the first of their many children was born on December 27th of that year. He moved to the village of Down, not far South of London, and resided there from September, 1842, until his death on April 19, 1882.

He had already published a semipopular account of his travels in 1839, usually called *The Voyage of the Beagle*; it was a great literary success. He also edited the scientific results of the voyage and published three books on the geology of the voyage, including one on coral reefs. He began to publish a few papers on zoology. One of these grew into a vast monograph on barnacles (Cirripedia). It was well over a thousand pages long, and consumed eight years of his working time.

The Origin of Species

At last, in 1854, the work on barnacles was completed and Darwin began to write a long book on evolution. It was to incorporate much original research as well as a detailed review of the literature. As it happened, Alfred Russel Wallace (1832–1913) was interested in the possibility of evolution too and spent many years in the field collecting animals and plants and studying their geographical distribution, first in South America (1848–1852) and then in the region that is now mostly part of Indonesia (1845–1862). They entered into correspondence and in a letter dated May 11, 1857, Darwin informed Wallace that he had an evolutionary theory but did not let on what it was. Wallace may have gained valuable hints from his readings of Darwin's publications, especially the book on the voyage, which contains among other things a brief discussion on Malthus. Nonetheless, he is generally credited with an independent discovery of the principle of natural selection.

A manuscript by Wallace on that topic reached Darwin in June, 1858 and his colleagues arranged for a joint publication, which was read at the Linnean Society on July 1. It became available in print the following month but was not well understood at that time. Almost immediately Darwin began an abstract of the longer book that he had been writing. This "abstract" became *On the Origin of Species by means of natural selection, or the Preservation of favoured races in the struggle for life*. Published on November 24, 1859; it became the focus of a controversy such as the world has never seen before or since.

As a supporter, Darwin already had his friend and confidant, the botanist Joseph Dalton Hooker (1817–1911) and others soon joined them. There were of course public debates, including the one at Oxford on June 9, 1860. Although the

exchange between Bishop Samuel Wilberforce (1805–1873) and Thomas Henry Huxley (1825–1895) is better known, Hooker was really more effective in support of Darwin's ideas. Darwin himself furthered his interests through behind the scenes negotiation and, more importantly, through research and publication. There were a total of six editions of the *Origin of Species*, the last of which was published in 1872.

Later Publications

Plans to complete and publish the big book were abandoned, but part of it, somewhat revised, appeared in 1868 as *The Variation of animals and plants under Domestication*. Concurrently Darwin had an active empirical research program under way, much of which was conducted on plants. His book of 1862, entitled *The various contrivances by which British and foreign orchids are fertilized by insects, and on the good effects of intercrossing*, dealt with the problems of adaptation. It was a seminal document of pollination ecology and the study of coevolution. Later works on floral biology, *The effects of cross and selffertilization in the vegetable kingdom* (1876) and *The different forms of flowers on plants of the same species* (1877) addressed mainly the effects of inbreeding and outbreeding.

Darwin was a first-rate plant physiologist, and his book *The movement and habits of climbing plants* had first appeared as a journal article in 1865; it was followed by *The power of movement in plants* (1880), which treated the underlying mechanisms of plant behavior. The book on climbing plants and *insectivorous plants* (1875) are early treatises in what later came to be called ethology. They deal with behavior from a comparative and evolutionary point of view. Treating humans, other animals, and even plants as part of an evolutionary continuum was a major contribution to comparative psychology, as well as a serious challenge to traditional philosophical ideas such as mind-body dualism. There was also a lot of behavior in *The descent of man, and selection in relation to sex* (1871) and its sequel, *The expression of the emotions in man and animals* (1872), and in the last of his books, *The formation of vegetable mold through the action of worms, with observations on their habits* (1881).

Darwin's work on sexual selection and the evolution of social behavior as treated in, *The descent of man* is strikingly modern in its approach. In retrospect, his efforts to solve the problems of heredity seem much less successful, though they stimulated others to work on them. It is unfortunate that his theory of pangenesis was appended to the 1868 book, *Variation*, with the result that it is rarely read because that theory was superseded. Although pangenesis explained the inheritance of acquired characters, it was more a theory of development than of heredity. In fact the book presents a remarkably sophisticated treatment of the relationships between embryology and evolution.

Darwin's Contributions to the Study of Biodiversity

The Competitive Natural Economy

Darwin succeeded, where others had failed, in convincing the scientific community that evolution had in fact occurred and

that it was responsible for the patterns of diversity that may be observed in both fossil and living organisms. Biogeography, paleontology, and classification took on a new significance, becoming profoundly historical in nature. He was less successful at gaining immediate support for his more fundamental (or at least original) contribution, which was the basic mechanism for evolution and the new way of thinking that went along with it. Evolution by natural selection made it possible to reject all sorts of older ideas about the world, especially the notion that organisms and the 'natural economy' have had somehow been designed, or produced by a supernatural agency. Darwin had demonstrated that there was much less 'purpose' in the world than had been supposed that there was nothing inherently 'good' about the way things are and that there was no necessary progression from lower to higher levels of organization.

Darwin's theory was immediately recognized as having profound philosophical significance. From time immemorial it had seemed natural to interpret the living world and the universe in general as if they were the product of something like human intelligence. Such notions and the anthropomorphic way of thinking that underlies them, are called 'teleology'. The idea that somehow the world had been designed or was otherwise the product of supernatural action was of course fundamental of much religious thinking, even among those who had come to accept early versions of evolution. The remarkable adaptations of living organisms were taken as evidence for the existence of a supernatural order. Although many of the features of inanimate nature could be explained in terms of laws of nature and matter in motion, a more subtle purposefulness was widely attributed to the universe as a whole. Indeed, the great German philosopher Immanuel Kant (1724–1804) had proclaimed that there never could be a 'Newton of the grass-blades' able to explain adaptation in strictly naturalistic terms. But that is precisely what Darwin accomplished.

Darwin also provided a way of thinking about adaptation that allows us to avoid the naive and anthropomorphic thought processes that lead to the illusion of design. Rather than asking what things are for, we ask how they might have evolved and explain the facts in terms of what has happened and why. When this is done properly, it becomes clear that much ascription of adaptive significance has been mere guesswork and that there is far less 'optimality' in the world than is sometimes supposed even today. However, research has repeatedly revealed that supposedly 'nonadaptive' features turn out to be very important in the lives of organisms. Defensive metabolites are an excellent example.

Opponents of Darwinism of course include many persons who have been reluctant to abandon teleological interpretations of nature. It has not always been a matter of denying evolution or natural selection outright. Often evolution has been envisaged as a means of achieving some supernaturally ordained plan. And often the teleology is merely assumed or presupposed rather than being advocated explicitly. 'Holistic' notions that treat the world as if it were a super-organism have a long history in myth and pseudoscience that goes back to antiquity. They retain their popularity among religious persons and advocates of occult metaphysics. Because such older ways of thinking are still widespread, it is important to avoid

giving the appearance of endorsing them. Functional explanations should be called 'teleonomic' (i.e., where the apparent purposefulness in organisms is derived from evolutionary adaptation) rather than 'teleological' and metaphors such as 'design' should be avoided.

The idea of progress has rarely been disassociated from teleological thinking. For that reason, among others, Darwin's ideas about progress have often been misinterpreted but rarely understood. They are often confused with quite different ideas, especially those of philosophers, social scientists, and non-Darwinian evolutionists. In pre-evolutionary biology it was widely accepted that organisms could be placed in a single series from lower to higher, connecting to nonliving matter at the bottom and to the various ranks of supernatural beings at the top. This great chain of being or *scala naturae* was later modified to make the order a historical or quasi-evolutionary one. Some authors treated the history of life as something like the development of an embryo and the succession of organisms would become increasingly more complicated because such change was in a sense built in to the ancestral germ. Others attributed the same basic pattern to laws of nature, laws that were supposedly preordained so as to have such an effect. In either case, it was Divine Providence on a geological scale.

Darwin forthrightly rejected that kind of progressionist thinking, especially as it had been presented by his predecessor Jean-Baptiste Lamarck (1744–1829) and his contemporaries Richard Owen (1804–1892) and Herbert Spencer (1820–1903). There was nothing like a cosmic escalator carrying species upward toward higher levels of organization. Nonetheless, Darwin believed that evolutionary progress is real and that his theory could explain it. He was well aware of the progress that had been made during his own lifetime in science and technology. Artificial selection was one technique by means of which domesticated breeds of plants and animals had been much improved. His study of the fossil record clearly indicated to him that analogous directional changes had taken place, even though Lyell and others had long denied that. Natural selection, he reasoned, would lead to the continued accumulation of adaptations that made their possessors increasingly able to compete with those around them. But he saw nothing truly inevitable about that kind of progressive change, for it depends on environmental and other circumstances that are not always realized.

Darwin replaced the older notion of a largely harmonious and cooperative natural economy with that of a fundamentally competitive one. The organisms within populations reproduce differentially as a consequence of how they utilize the resources in their environments and change occurs in the direction of more effective use of those resources. That accounts for adaptation and for such progressive and regressive changes as may in fact occur. But it greatly limits the kind of adaptation that can evolve, because it is organisms, and to some extent families, that compete as reproductive units. Darwin was profoundly aware of the point that his mechanism would not produce adaptations at the species level or at the level of the community or ecosystem. This point, however, was often neglected by his contemporaries and received due emphasis only in the latter half of the twentieth century.

Darwin's idea of what a species is lacked a clear conception of reproductively isolated populations with distinct gene pools.

Furthermore, he did not fully appreciate the difference between genotypic and phenotypic variability. Because his mechanism depended on differences between individual organisms, he needed to show that the necessary variability does in fact exist. He was able to show that species are indeed far more variable than his predecessors had believed. He also discovered that sexual reproduction and outcrossing are much more prevalent than even he had at first suspected. Therefore, his contributions to the study of population structure in nature were the foundation for a great deal of work along such lines.

Variation within and between the component populations of a species is one important form of biodiversity within species. Another is the sort of differences that may be observed between the sexes, and here again Darwin's contribution was fundamental. His theory of sexual selection helped to account for sexual dimorphism on the basis of males competing for the females, either through fighting with one another or through efforts to attract the females. He also discovered heterostyly in plants. This is a kind of polymorphism in which hermaphrodite flowers of the same species have different morphologies, furthering outcrossing and reducing inbreeding.

Darwin also was able to explain the global pattern of diversity among species. Of course the splitting up of species and their ability to undergo an indefinite amount of change allows diversification through geological time. However, that by itself does not tell us why or how the diversification takes place. To account for that Darwin invoked what he called a 'principle of divergence of character.' According to this principle, diversification allows the organisms to exploit a wider range of resources, so that groups of them can expand their numbers. As he put it, they can occupy more places in the natural economy, or as we would say, they can occupy more Eltonian niches. It is important not to view this diversity in a strictly negative way, as if it was merely a matter of 'avoiding competition.' Rather, new resources come to be exploited and the original ones may be exploited more effectively.

Darwin was also one of the first scientists to study competition experimentally. In *The Origin of Species* he described field experiments that document changes in diversity as a result of competition. He believed that competition is most severe between closely related organisms, and this tends to drive both intermediate forms to extinction and to bring about divergent evolution among the more modified ones. At lower taxonomic levels this means that higher biotic diversity should develop where the competition is most severe, notably in the tropics. At higher taxonomic levels, it means that there is adaptive radiation within groups such as families, orders, and classes. The lack of intermediate forms among extant taxa is the consequence of those forms that were close to the ancestral ones having been driven to extinction. On a global scale, whole biotas would tend gradually to diversify through time. Darwin specified the conditions under which such diversification would lead to the evolution of competitively effective organisms. These included a large area and a diverse topography, coupled with a long period of competitive interaction among the inhabitants. He realized that the biotas of separate biotic provinces have not undergone the same amount or kind of modification and that similar considerations apply to insular biotas. His insights were thus fundamental to our understanding of invasions, faunal interchanges, and many aspects of extinction.

Darwin contributed a great deal toward our understanding of the interdependencies among species by emphasizing how complicated such ecological relationships may be. He was particularly interested in pollination symbiosis and his work in that area initiated the study of coevolution among animals and plants. Although his research was focused on showing the importance of outcrossing, it also revealed the ecological significance of pollination.

Classification

Systematics is often defined as the study of biodiversity and Darwin made fundamental contributions to both the theory and the content of that science. Classification is part of everybody's language and thinking and is necessary for the organization of knowledge, whether it be the knowledge of a lay-person or a professional scientist. The objects of our experience can be referred to by more or less general terms, such as 'food,' 'pasta,' and 'spaghetti.' Because what is true of the more general groups is true of all the groups that fall under them; we have a powerful instrument for thinking about more than just single objects. If pasta is made of grain, and all spaghetti is pasta, then spaghetti is made of grain.

Scientific classification may be much more sophisticated than that of the lay-person. Scientists attempt to discover groups of things that share properties that are of theoretical importance. A good example of a scientific classification system is the periodic table of the elements, in which chlorine and bromine are both halogens and undergo similar chemical reactions. The groups in question may be worked out on an empirical basis, and only later understood in theoretical terms. This was approximately the case with Darwin's work on biological systematics. Human beings could be assigned to more general groups, such as mammalia, vertebrata, and animalia but it was not obvious why. Sometimes it was attributed to God having some plan in mind when He created organisms, and sometimes unknown laws of nature were thought to be responsible.

Darwin's solution to this puzzle was straight-forward and evolutionary. According to his biodiversity model, species have repeatedly undergone a kind of splitting, giving rise to separate lineages that evolve more and more differences as time since common ancestry becomes greater. The more general the group, the earlier the common ancestry. Once the theoretical reason for traditional classification was understood, a new approach could be developed in which the groups were explicitly recognized as lineages sharing a common ancestor. As Darwin put it: 'Our classifications will come to be, as far as they can be so made, genealogies.'

Putting that prognostication into practice was not easy and, generally speaking, classifications have been only rough approximations to genealogies. They also generally attempt to express the amount of difference that separates the various groups, and sometimes the criteria conflict. Be this as it may, Darwin was writing from his experience. On October 1, 1846, he began to study the anatomy of barnacles in order to write a short paper on an aberrant species that he had discovered. The project expanded to the point that he spent eight years revising and monographing the entire subclass, both living and fossil,

and treating all aspects of their biology in great detail. Although he did not explain what he was doing at the time, it is clear that his classification is based on his understanding of the phylogeny of the group. Subsequent workers have modified and enlarged his system, but the basic arrangement remains the same. Why Darwin delayed publishing his evolutionary theory in order to undertake a major research program in systematics has been somewhat of a puzzle to historians. One possible reason, however, is quite clear. He was interested in topics such as the evolution of organisms with separate sexes from ancestral hermaphrodites. The problems were solvable, but only if the sequence of changes could be documented, and that meant reconstructing the pattern of branching in the phylogenetic tree. Without good systematics, much of evolutionary biology would consist of untested hypotheses and conjectural history. This is as true today as it was for Darwin.

Because, as was already mentioned, Darwin did not have an adequate species concept, modern systematists have made some important changes in Darwin's barnacle classification. In particular, many of the groups that he treated as mere varieties are now classified as species. In many other respects, however, his approach was very advanced for his day. He worked with extensive series of specimens and went out of his way to document all kinds of variation.

Darwinism after Darwin

Alternatives to Darwinism

Darwin maintained that natural selection is the 'main but not exclusive' evolutionary mechanism. This seems about as good a criterion as any for distinguishing 'Darwinians' from a wider range of scientists who accepted evolution but either rejected natural selection or treated it as unimportant relative to other causes. Among these scientists, the followers of Jean-Baptiste Lamarck (1744–1829), who emphasized use and disuse, were particularly numerous. However, there were other alternatives. Étienne Geoffroy Saint-Hilaire (1772–1844), whose views are often confused with those of Lamarck, believed that the environment directly induces changes in structure. Indeed, Darwin was strongly influenced by Geoffroy and accepted the direct action of the environment as a minor cause of change. There were also various versions of 'orthogenesis' or evolution that is directed in a particular direction. Some versions of orthogenesis were based on the notion that evolution is like embryological development and change has been built in from the start. In other versions, laws of nature, similar to those that determine the structure of minerals, were invoked. Sometimes the appeal was to unknown causes, perhaps of a supernatural character. Many scientists were, or at least claimed to be, agnostic with respect to what causes evolution.

Early Darwinians

Given such a range of alternatives and the small amount of research that had been done, it makes sense that from the outset there were few Darwinians other than Darwin himself. Because he was largely responsible for getting evolutionary

thinking in general accepted by the intellectual community, a lot of evolutionists who did not accept natural selection nonetheless considered themselves his followers. The degree to which Darwinism, in the sense that we use that term here, was a minority position has sometimes been exaggerated. We can identify quite a number of important contemporaries of Darwin who established successful research programs based on the study of natural selection. Foremost among these of course was Alfred Russel Wallace (1832–1913), its codiscoverer. Also very distinguished was Wallace's traveling companion, Henry Walter Bates (1825–1892), the discoverer of Batesian mimicry. Second only to Darwin in his mastery of the theory was Fritz Müller (1822–1897). He is best remembered for his discovery of Müllerian mimicry, but he also was the first to propound the idea that developmental stages may recapitulate evolutionary ones. Both Fritz Müller and his brother Hermann (1829–1883) conducted magisterial research on pollination symbiosis under Darwin's influence. It is worth emphasizing that these scientists were outstanding for their performance as naturalists in the field. The kind of research that they did has been fundamental to our understanding of biodiversity because it documents how natural selection takes place in real environments.

Darwin also had important followers whose work was more focused in the museum and the laboratory. He had a close circle of followers, botanist Joseph Dalton Hooker (1817–1911), zoologists George John Romanes (1848–1894), and John Lubbock (1834–1913). There was also August Weismann (1834–1914), whose ideas about the continuity of the germplasm made natural selection seem a much more plausible explanation for evolution than Lamarckism. Neo-Darwinism is rightly associated with the name of Weismann, whose basic position was that natural selection is not just the main but the exclusive evolutionary mechanism. Actually he admitted two minor ones that had been invoked by Darwin: sexual selection and pleiotropy.

Genetics and the Modern Synthesis

Beginning in 1900, Mendelism, developed from the revolutionary research of Gregor Johann Mendel (1822–1884), began to supply the understanding of heredity that Darwinism needed. However, it did not have the immediate effect of gaining adherents to Darwin's theory. Instead it gave rise to alternatives such as mutationism. Advocates of mutationism were more impressed by conspicuous mutants and erroneously concluded that their sudden appearance in a single generation could be extrapolated to the origin of new species and even higher taxa. However the study of genetics soon moved away from mutationism and gradually undermined some of the other alternatives, especially Lamarckism and orthogenesis.

The reconciliation of Darwinism with genetics depended in part on the elimination of such alternatives, in part on the growth of theoretical population genetics, and in part on the study of natural populations in the field. Studies of natural populations by systematists like Ernst Mayr (1904–2004) and geneticists like Theodosius Dobzhansky (1900–1975) were crucial to the 'evolutionary synthesis' that began in the 1930s

and matured by around 1950. A new and more sophisticated biological species concept emerged and the richness of genetic diversity within populations became much better understood. The result was a theory very much like Darwin's but without the minor elements of Lamarckism and Geoffroyism integrated with modern genetics.

This modernized Darwinism continued to be expanded and refined. Regarding biodiversity, there were two important developments, both of which involved a return to Darwin's original theory. First, there was Darwin's ecology, which was based on individualistic competition and which rejected the notion that organisms do things 'for the good of the species' or 'in order to benefit the ecosystem.' Ecologists had commonly treated species and ecosystems as if they were super-organisms and had attributed a kind of adaptation to them that could only have resulted from selection of populations. The rejection of 'group selection' in its unsophisticated and uncritical form was largely carried out in the 1960s and 1970s.

Second, there was a return to Darwin's idea that classification should be genealogical. Although both the extent and the manner to which this program should be carried out have been controversial, it is generally agreed that comparative biology is best conducted within the framework of phylogenetic relationships. Ill-defined 'similarity' has proved to be too subjective and not rigorous enough for modern biodiversity research. This development has partly been the result of new methodologies (especially cladistic analysis). It has also been strengthened by new kinds of evidence, such as isozyme studies and genomic sequencing that supplement the more traditional data.

Contemporary Developments

From time to time Darwinism and neo-Darwinism are challenged by what are purported to be genuine alternatives. Some of these challenges, such as efforts to resurrect Lamarckism or orthogenesis, have simply not measured up. Others, such as developmental constraints, are components of Darwinism that may not have received as much attention as they deserve. Still others, such as the notion of punctuated equilibria, with its occasional periods of rapid change interspersed with long interludes of stasis, are by no means incompatible with the Darwinian tradition.

Darwinism has never been so monolithic or devoid of major unanswered questions as to preclude a broad range of

possibilities for new developments. At present it is by no means clear to what degree processes at various levels need to be invoked to provide a satisfactory account of evolution. The 'reductionist' view that would explain everything in terms of genes and essentially ignore organisms and species is obviously too simplistic. The models used in theoretical population genetics make all sorts of unrealistic assumptions and more realistic ones might give surprising results. There is still no satisfactory explanation for the prevalence and ecological patterns of sexuality. In spite of much recent progress, many of the traditional problems of phylogenetics remain highly debatable. Much work remains to be done in turning branching phylogenetic diagrams into explanatory historical narratives. The vast majority of extant species remain undescribed and the fossil record consists largely of 'roadkills' strung together with gaps. There are plenty of opportunities for important new discoveries within the Darwinian research tradition.

Glossary

Chemical defenses Compounds used by plants to deter or poison herbivores and pathogens.

Constitutive defenses Defenses that are manufactured and maintained by a plant, regardless of whether it has been attacked by an herbivore or pathogen.

Endophyte Fungus or other organisms residing or growing within plant tissues.

Herbivory Damage to plant tissues by herbivores or pathogens.

Induced defenses Plant defenses, including both chemical and physical defenses, that are produced, at least in their final form, only after the plant has been damaged by herbivores or pathogens.

Mutualism Interactions between organisms of different species that increase the fitness of both participants.

Secondary compounds A synonym for chemical defenses in plants; contrasts with chemical compounds used in primary metabolism, such as photosynthesis and cellular respiration.

Diversity and Function of Chemical Defenses

Plants contain a tremendous diversity of chemical compounds that have no function in any aspect of primary metabolism, such as in cellular respiration or photosynthesis. Therefore, these compounds are frequently called “secondary compounds” and were originally thought to be either waste products or storage molecules. In the 1950s, however, it was realized that these compounds were in fact defenses against herbivores and pathogens. There is an impressive variety of forms of these compounds, and we begin with a brief description of the more common types and how they act. For additional details, see Rosenthal and Berenbaum (1991) and Harborne (1988) (Table 1).

Phenolic Compounds

Perhaps the most common chemical defenses in plants are composed of phenols. Simple phenols consist of a benzene ring with a hydroxyl group attached, along with varying functional groups. More than 200 different simple phenols have been described, and they have been found to deter feeding of both invertebrate and vertebrate herbivores. Several studies have shown that plants with higher concentrations of phenolics were avoided by species of herbivorous birds (Harborne, 1988).

For example, the Canada goose selects plant species that are low in phenolic content, and in the subarctic phenolic resins deter the feeding of ptarmigans and grouse on several plant species. In the latter case, the resins may be effective defenses because they have antimicrobial effects and may disrupt digestion by microbes in the birds’ caeca.

Compounds composed of multiple phenolic units are called tannins, most of which belong to either of two groups. Hydrolyzable tannins have relatively simple structures that are made up of phenolic acids, whereas condensed tannins (also called proanthocyanidins) have more complicated structures and are made from the condensation of hydroxyflavanol units. Condensed tannins are also more common across plant taxonomic groups, occurring in 54% of angiosperm and 74% of gymnosperm genera that have been examined. In contrast, hydrolyzable tannins are found in only 13% of angiosperm genera (all dicots) and are absent from gymnosperms. Although the actual mechanism of tannin action is controversial, tannins may function by binding proteins. As a herbivore chews a leaf, the tannins stored in the leaf vacuole are released and mix with the proteins, binding them and rendering them indigestible. Since proteins are a primary source of nitrogen for herbivores, this chemical reaction makes leaves less nutritious, although it is unclear whether this reaction is effective in the digestive tract of herbivores.

Table 1 Types of chemical defenses in plants

<i>Class of compound</i>	<i>Activity</i>	<i>Examples</i>
Alkaloids	Variety of mechanisms; often disrupt nervous system function	Caffeine, nicotine, morphine
Nonprotein amino acids	Disrupt proteins when incorporated in herbivores	Canavanine
Phenolics	May bind proteins, reducing the nitrogen available to herbivores	Hydrolyzable tannins and condensed tannins
Saponins	May reduce uptake of sterol from herbivore digestive system	Digitonin
Terpenes	Various; often toxic	Pyrethroids, hormone mimics
Toxic proteins	Variety of mechanisms; highly toxic compounds	Ricin

Nonetheless, evidence suggests that tannins do deter feeding and are even toxic to some herbivores.

Alkaloids

Though a structurally and biochemically diverse group of secondary compounds, all alkaloids have a heterocyclic ring that either contains a nitrogen atom or has one attached to it (Roberts and Wink, 1998). Some of the best known include atropine, the main poison in deadly nightshade (*Atropa belladonna*), quinine, caffeine, cocaine, morphine, and nicotine. It has been estimated that between 15 and 20% of all vascular plants contain alkaloids, and that they are found in one-third of angiosperm families, primarily the dicots. The distribution of alkaloids in relation to climate or geographic distribution remains in dispute, but in general it appears that alkaloids are a more common form of defense in tropical habitats than in the temperate zone. About 16% of temperate species in one survey contained alkaloids versus 35% of tropical species. The mechanisms by which alkaloids affect herbivores (including humans) are highly varied and specific and often effective at small doses, making them effective poisons (see Human Uses of Plant Defenses). Many that have been described affect the functioning of the autonomic nervous system by competing with neurotransmitters. An alkaloid found in the genus *Erythrina* (Fabaceae) blocks acetylcholine receptors in animals, whereas caffeine, an alkaloid found in *Coffea arabica* (Rubiaceae), causes the release of calcium from neural receptors. Both types of disruption can lead to the death of susceptible herbivores.

Terpenes

These are an extremely heterogeneous group of chemicals derived from a common metabolic pathway that produces polymers of isoprene units, a five-carbon compound. The isoprene units may then be arranged in a variety of ways, generating a diverse range of nonpolar compounds. Monoterpenes, which have 10 carbon atoms, are often volatile and include pyrethroids from the genus *Chrysanthemum* that are highly toxic to insects and used as commercial insecticides. These neurotoxins disrupt sodium channels in neurons, causing uncoordinated movement and paralysis. Sesquiterpenes, diterpenes, and triterpenes are larger polymers containing 15, 20, and 30 isoprene units, respectively. Terpenes are especially common in pine and fir trees, which secrete the chemicals in resins that reduce insect attack, although monoterpenes can act as feeding attractants for some species of beetles.

Terpenes can be combined with other molecules to form additional types of secondary compounds, for example, sesquiterpene lactones. In this case, a lactone ring (composed of three carbon atoms, with an oxygen and a carbonyl group) is attached to a sesquiterpene. These compounds are found predominantly in the family Asteraceae. Studies have shown that they are toxic to a variety of herbivorous insects and mammals, particularly livestock. Currently, the cause of the toxicity of sesquiterpene lactones is not known, although they cause tissue lesions in mammals and may disrupt hormone function in insects.

Another group of compounds that are chemically related to triterpenes have the remarkable feature that they can act as analogs to hormones found in animals. These analogs do not appear to have any function in plant metabolism, but their similarity to animal hormones is so striking that it is easy to believe that they evolved primarily as a defense against herbivores. Among these plant hormones are mimics of human female sex hormones, and these plant “phytoestrogens” are being used as alternative medicines.

Some plant species also produce analogs that mimic insect hormones. Two critical hormones in insects are juvenile hormone and molting hormone, both of which are necessary for the development of larvae or juveniles. Molting hormone mimics (or phytoecdysones) are common in ferns and gymnosperms (but rare in flowering plants) and, when consumed by insect larvae, disrupt hormonal control of development, in some cases causing death by preventing the insect from shedding its cuticle. Juvabione and other analogs of juvenile hormone are less common than mimics of molting hormone but appear to have similar, fatal effects in insects.

Three other important groups of terpenes are cucurbitacins (found in the family Cucurbitaceae), limonoids (found in Rutaceae, among others), and saponins, which are discussed in the following section.

Saponins

A type of triterpenoid glycoside, saponins are complicated molecules composed of a polycyclic structure (with either 27 or 30 carbon atoms) attached to a carbohydrate group. Consequently, these molecules have both hydrophobic and hydrophilic properties, making them water soluble. Taxonomic surveys suggest that saponins are widespread; one study found that they are present in 500 species from 80 plant families. Saponins have been shown to be toxic to many arthropods, including mites, beetles, and lepidopterans. In insects, saponins may reduce the uptake of sterol from the digestive system. Since sterol is necessary for insects to molt, saponins apparently interfere with insect development. There is little evidence, however, that saponins are toxic to most mammals.

Nonprotein Amino Acids

Many plant species produce amino acids that are not used in making proteins but instead are involved in defenses against natural enemies. More than 600 of these nonprotein amino acids have been identified from a wide range of plant species. For example, canavanine, a structural analog of the amino acid arginine, has been found in 1500 species in the legume family. Fed to sensitive insect herbivores, canavanine causes dramatic and often fatal defects in development. This effect occurs because canavanine becomes incorporated into newly synthesized proteins in place of arginine, thus altering their structure and function. A species that produces canavanine, the woody vine *Dioclea megacarpa*, has seeds that are 8% canavanine by dry weight. Not surprisingly, these seeds are largely free from attack except by one specialized beetle (Rosenthal and Berenbaum, 1991).

Toxic Proteins

Plants also make toxic defensive proteins that produce their effects through a variety of different mechanisms (Kiowa *et al.*, 1997). One such protein, ricin, is produced by the castor bean (*Ricinus communis*) and functions by inhibiting ribosomes in herbivores. By weight, it is among the most toxic compounds known. In general, there is considerable interest in identifying genes that code for toxic proteins in wild plants. If such genes could then be used to modify agricultural crops, they would be protected from herbivores without the use of chemical insecticides.

Physical and Structural Defenses

Spines

In addition to chemical defenses, plants also employ a wide range of physical or structural features that either reduce the accessibility of plant tissue to herbivores or deter herbivore feeding. The most apparent of these are spines or thorns on plants. There is little doubt that the primary function of these structures is as a defense against herbivorous animals, particularly vertebrates, although in some cases spines may help plants to thermoregulate or, in the case of some vines, to climb.

Trichomes

In some ways resembling small spines, trichomes are structures found on the leaves and stems of many plant species that inhibit attack by herbivores and pathogens, either physically or chemically. The shapes and sizes of trichomes vary considerably across species from slender hairs to stout spikes, and many are armed with recurved barbs. Furthermore, glandular trichomes of many species produce or store chemicals that act as deterrents to herbivores. There are countless examples from plants in both natural and agricultural settings of how trichomes can kill or deter herbivores (Levin, 1973). Acting as physical barriers, trichomes can reduce egg laying by herbivores on some varieties of wheat and increase plant resistance to leaf hoppers and mites in some varieties of cotton. The chemicals secreted by many trichomes include sticky gums that immobilize small insects, as found in some varieties of wild potato and tomato. On other species trichomes secrete chemicals such as alkaloids and terpenes as well as waxes, fatty acids, and alcohols. These chemicals are frequently toxic to herbivores, for example, nicotine (an alkaloid) secreted by tobacco plants (*Nicotiana* in the Solanaceae) that kills aphids on contact. Thus, trichomes not only act as physical defenses but also provide a way for plants to use chemical defenses against their natural enemies without first having to suffer tissue damage.

Toughness

Leaves with thick cell walls, consisting of lignin and fiber, are tough. In one assessment of both physical and chemical defenses of mature leaves in tropical forests, leaf toughness and

fiber content were the two most important factors in reducing herbivory. Toughness is an effective defense against insect herbivores, particularly small or immature ones, because they have a difficult time cutting or chewing the leaves. Furthermore, cell walls are largely indigestible; therefore, tough leaves are nutritionally poor.

Biotic Defenses and the Third Trophic Level

In addition to using chemical and physical defenses against herbivores and pathogens, many plant species have evolved complex, mutualistic interactions with other groups of organisms that act as a type of defense against herbivores. In such interactions, the plants typically provide food, shelter, or both, whereas the other organisms defend the plant from its natural enemies.

Ants

The best studied defensive mutualisms in plants are those with ants (Huxley and Cutler, 1991). Given the incredible abundance of ants in most habitats and their propensity to forage on leaves and stems, it is not surprising that these mutualisms are so common. Ant–plant interactions vary from loose, facultative associations in which the plant offers rewards to any ants in its vicinity to more tightly coevolved relationships in which both partners display highly specialized traits. In facultative associations, a plant offers nectar, food bodies, and other rewards to lure ants that nest elsewhere to patrol its leaves and remove any herbivores they encounter. These associations are especially common in tropical forests.

There are also many obligate ant–plant mutualisms, in which one or both participants require the other to survive. The best known is the interaction between the tree *Acacia cornigera* (Fabaceae) and the ant *Pseudomyrmex ferruginea* (Pseudomyrmecinae) in Central America. The plants in this pair have numerous adaptations for playing host to the ants, including swollen thorns on which the ants have their colonies, enlarged nectaries on the leaves that provide the ants with sugars, and modified leaflet tips on which the ants can feed. The young queen ant establishes a colony by landing on a young tree and setting up a nest in one of the swollen thorns. After the colony is established, the worker ants patrol the tree constantly, removing any other insects on the tree and cutting away any other plants that touch it. In one study, when the ants were experimentally removed the plants suffered high rates of defoliation, leading to a reduction in growth and a doubling of mortality during the 11 months of the study (55 vs 28% for control plants with ants). Thus, there is little doubt that ants can play an important role in protecting plants in these tightly obligate mutualisms.

The clear defensive effect of ants on their host plants has been demonstrated for other species as well. Less easily measured is the cost of the ants as a defense: Presumably the benefits outweigh the costs, but what are they? Recent studies show that *Cecropia* trees produce different types of food rewards for their ants in relation to the nutrients available—in effect producing rewards that use the less limiting nutrients. Circumstantial

evidence also suggests that the ants are a costly defense since on islands on which native ants are rare or absent, few plant species have either extrafloral nectaries or food bodies.

Domatia, Mites, and Other Predators

The mutualistic relationship between ants and plants is apparently paralleled by similar but looser associations between plants and small arthropods. Many plant species have structures on their leaves called domatia that can serve as homes for mites and small, predaceous insects. Although there are a variety of forms, most domatia are pits, pockets, or tufts of hairs on the undersides of leaves. Domatia are widespread taxonomically among dicots, occurring in 28% of 290 plant families, and they are quite common, at least in some forests. Recent work has supported the hypothesis that domatia provide shelter to arthropods, which in turn attack herbivores on the plant. For example, when artificial domatia were placed on the leaves of cotton plants, the density of predaceous bugs increased, the number of herbivores decreased, and the number of fruit produced increased by 30%. Although preliminary, this work suggests that domatia are a part of loose mutualisms used by plants to defend themselves.

Endophytic Fungi

In addition to using animals as a means of defense against herbivores and pathogens, there is considerable evidence that plants can employ fungi in a similar manner. Most plants are infected asymptotically by endophytic fungi—that is, fungi that live within the plant, usually between the plant cells. These endophytes are a potential defense since they produce chemical compounds not made by plants.

Although endophytes are common in an impressive diversity of plant species, most research has focused on their relationship with grasses. In fact, their defensive role in plants was only appreciated after it was discovered that cattle suffered toxic symptoms after eating tall fescue grass infected with a fungal endophyte. Since then, grasses infected with fungal endophytes have been shown to be toxic to other domestic and wild mammalian herbivores as well as herbivorous insects. At the community level, research has shown that pastures dominated by endophyte-infected grasses have lower populations of small mammals. Thus, it seems likely that plants can gain some protection against herbivores from fungal endophytes.

Predators and Parasitoids as Plant Defenses

Plant defenses have evolved within ecological communities in which predators and parasitoids that attack their herbivores are often common. Evidence suggests that some plant species may directly or indirectly elicit the help of these predators and parasitoids as a form of defense. Recent research has found that some plants release volatile compounds when damaged, and that these are used as location cues by parasitoids and predators (Turlings and Benrey, 1998). Frequently, these volatile chemicals are emitted only when damage is accompanied by oral secretions of herbivores, meaning that the

signals are specifically released when a herbivore is present and not when the plants incur other types of damage. By facilitating the discovery of herbivores by their predators and parasites, plants may enjoy reduced herbivory.

Other defenses, such as tannins and toughness, do not kill herbivores outright but reduce their growth and prolong the time until pupation. As a result, herbivores may actually consume more leaf tissue than if the plants lacked these defenses. This seems paradoxical, but by slowing growth these defenses increase the chance that herbivores will be preyed on while still in the earlier instars (Benrey and Denno, 1997). Since the majority of leaf damage occurs in the final instar, this could greatly reduce herbivory. Thus, the effectiveness of some defenses may depend critically on help from parasitoids and predators.

Phenological Strategies

New, expanding leaves are generally more vulnerable to attack by herbivores and pathogens than mature leaves because they are tender and nutritious. In addition to the defenses already described, many plant species reduce new leaf damage by altering the timing of new leaf production. These phenological strategies are of two general types. In the first, plants produce new leaves during times of the year when herbivores and pathogens are rare. In temperate forests, the spring flush of leaves occurs during the short window of opportunity between the end of winter and the recovery of herbivore populations in the late spring. Similarly, studies conducted in tropical forests in India, Ghana, and Panama have shown that when plants produce new leaves during the dry season, when herbivores are rare, herbivory is reduced. Obviously, this seasonal escape strategy would not work in nonseasonal climates, and because of coincident changes in light and water availability with season it is difficult to demonstrate conclusively that the timing of leaf production is mainly an adaptation to reduce herbivore and pathogen damage.

The second phenological strategy to decrease damage to new leaves is for the plants of a given species to produce new leaves synchronously. By flushing simultaneously, plants may be able to overwhelm their specialist herbivores with an abundance of new leaves so that the chance that any particular new leaf will be discovered and eaten is decreased. One test of this strategy involved following new leaf production and herbivory in a moist tropical forest for a year. The results showed that highly synchronous species experienced lowered herbivory than those that were continuous in production. This phenological strategy may be more important in less seasonal forests in which a seasonal escape strategy may be less effective.

Plant Investments in Defenses

Assumptions

In their evaluations of plant defenses, ecologists typically make the following assumptions: (i) Herbivory and other tissue damage by natural enemies is bad for plants, reducing their fitness; (ii) defenses reduce damage by natural enemies;

and (iii) defenses cost the plants in terms of energy and nutrients.

Surprisingly, the first assumption about the negative effect of herbivory on plants has been controversial. Several studies have shown that some plant species, in certain circumstances, are able to “overcompensate” for tissue damage, achieving higher fitness than those that were never damaged. However, in general the evidence is quite clear that herbivory, for most plant species, reduces fitness. The billions of dollars spent annually throughout the world on pesticides to protect crops are a testament to the negative effects of herbivores and pathogens. Experimental studies have also demonstrated that damage reduces plant fitness. In a study by Marquis, for example, shrubs of the species *Piper arieianum* (Piperaceae) were artificially defoliated and their growth and seed production followed for 2 years. The results showed that individuals that had lost at least 30% of their leaf area suffered a 50% decrease in growth and produced approximately half the seeds of control plants. Clearly, damage affects plant fitness.

Costs and Benefits of Defenses

Plant defenses may be costly to plants for several reasons (Fritz and Sims, 1992). First, in order to invest in defenses, plants must divert resources from other aspects of growth and reproduction. For example, nitrogen that a plant invests in alkaloids as a defense cannot be used in making proteins necessary for greater photosynthesis. A second reason why defenses may be costly to plants is that some chemical defenses, although effective deterrents against natural enemies, may also be toxic to the plant, so the plant has to expend additional energy protecting itself from its own defenses. Tannins must be sequestered in the vacuole to avoid cell damage, and many terpenes and resins are restricted to specialized canals in plants.

Third, a defense that reduces plant damage from one herbivore or pathogen species may inadvertently make the plant more attractive to another. For example, Eisner and coworkers showed that the trichomes on the leaves and stems of *Mentzelia pumila* (Loasaceae) frequently ensnare a variety of insects, including many damaging herbivores. However, the trichomes do not affect a damaging aphid species, whereas they kill one of its predators. Thus, the trichome defense protects the plant from some herbivores but makes it more vulnerable to others.

Despite a variety of direct and indirect costs of defense, plants generally benefit from being defended from herbivores and pathogens. One instance was already discussed: When the ants were removed from ant-defended *Acacias*, herbivory and plant mortality increased. Other studies of chemical defenses have shown the benefits of chemical defenses as well as their costs. One such study was conducted by Berenbaum and associates, who examined whether wild parsnips benefited from being chemically defended in the presence of the herbivore parsnip webworms. They showed that plants with greater chemical defenses had higher fitness in the presence of the webworms, meaning that the defenses had a clear benefit. The chemicals were costly, however, because in the absence of herbivores in the greenhouse plants that were better defended

chemically had lower seed production. Under natural conditions, however, the benefits of reduced herbivore damage outweighed the costs to these plants.

Induced Defenses

The chemical defenses described so far are usually constitutive—that is, they are produced and maintained regardless of whether herbivores or pathogens have damaged the plant. Many secondary compounds, however, are induced, with production (or at least the final stages of production) only occurring after the plant has been attacked (Karban and Baldwin, 1997). Usually, an aspect of damage, such as partially eaten cell walls, leads to a transduction process that causes the cell, tissue, or whole plant to begin synthesis of defensive compounds. This entire process can take place in less than 1 hr. In field and laboratory conditions, plants that have been induced suffer less herbivory and have higher fitness than controls. However, most species do not appear to have inducible defenses.

Plants should have induced defenses instead of constitutive ones if defenses are costly to plants, and energy and nutrients that are allocated for secondary compounds or other compounds cannot be used for growth or reproduction. Therefore, by producing defenses only when they are needed—during an attack by herbivores or pathogens—the plant is able to divert these resources to growth and reproduction. However, most species do not appear to have inducible defenses, suggesting that plants may frequently not be in the position to predict when it would be advantageous to induce defenses.

Theories of Plant Defense

Both across and within habitats, the amount of damage that plants suffer from herbivores and pathogens varies enormously. In a tropical forest, for instance, rates of herbivory to mature leaves can vary more than two orders of magnitude, from species that receive virtually no damage to those that lose more than 0.6% of their leaf area per day. This huge range implies that plants differ in both the types and amount they invest in defenses.

Much research has focused on trying to correlate defensive investment with other plant life history traits and habitat preferences. It is generally accepted that short-lived, fast-growing species, which typically are found in resource-rich habitats, are not as well defended as slower growing, longer lived woody species. However, the underlying reasons for these patterns are not understood, and numerous theories have been proposed. Two important elements appear in many of these theories: value and risk. First, selection should favor high investments in defense if the risk of herbivory is high. Second, effective defenses should be favored in tissues with a high value or replacement cost.

Apparent theory was the first influential attempt to provide a theoretical framework for plant defenses (Feeny, 1976). It emphasized differences in the risk of herbivory, arguing that defense investment should depend on how apparent plants are to herbivores. Species that are ephemeral, such as annuals, may not be readily apparent to herbivores, whereas long-lived

trees and shrubs should be readily found. Thus, unapparent plants should be able to largely escape specialist herbivores and, as a result, should invest less in defenses and use defenses that are toxic at low concentrations to generalist herbivores. These “qualitative” defenses include low-molecular-weight compounds such as alkaloids, cyanogenic glycosides, and monoterpenes. In contrast, apparent plants are certain to be discovered by host-specialist herbivores and should produce leaves that are generally less palatable. The theory predicts that they should invest in “quantitative” defenses, such as tannins and toughness, that are not poisonous per se but have dosage-dependent effects, making leaves harder to digest. One test of this prediction found that herbaceous plants had a greater abundance of toxic alkaloids than more apparent, woody plants. Several authors have also suggested that the risk of discovery by herbivores may depend on the frequency of other more palatable species in the community.

Other theories, although acknowledging that herbivore pressure is important, also suggest that the value of the plant tissue should influence the evolution of defense. For example, species adapted to resource-poor environments, such as those with low light or poor soils, have inherently slow growth rates and long leaf lifetimes. The resource availability hypothesis (Coley *et al.*, 1985) argues that slower growing species should invest more in defenses than fast-growing ones because the cost of replacing damaged leaves is higher when resources are limited. Moreover, in slow growers, the decrement of lost growth for a given investment in defenses is small because the species are already growing slowly. However, in a fast growing species, the investment in defenses leads to a higher percentage decrease in plant growth. This means that the relative or opportunity cost of plant defenses is greater for fast-growing species than for slow growers. Thus, for a given abundance of natural enemies, plant species adapted for growth in high resource environments should maximize their growth by investing less in defense and suffering greater herbivory. The optimal level of defense for species adapted to low resource environments should be much higher.

The resource availability theory also predicts the general types of defenses that plants should use. Species with long-lived leaves should invest in defensive compounds that, despite high initial costs due to their high concentrations, have low turnover rates. These defenses include fibers, which increase leaf toughness, and tannins, both of which would be quantitative defenses in the plant apparency theory. In fast-growing species with short-lived leaves, these defenses would not be profitable because the leaves would be dropped before the plants would have an opportunity to recoup their investment. Instead, the hypothesis predicts that species with short-lived leaves should invest in compounds that are effective at low concentrations even though they may have high turnover rates. The combination of low concentration (or low incremental cost) and high turnover rates means that these defenses are relatively less costly to plants that have short-lived leaves, especially because the components of these defenses can be withdrawn from leaves before they senesce. These defenses would be very costly for species with long-lived leaves since they would have to be continually regenerating these defenses over a long period of time.

Plasticity in Defenses

The theories of plant defenses presented in the last section attempt to explain why selection would favor different amounts and types of defenses in different species. An underlying assumption is that defense strategies will be optimized for the predominant conditions experienced by each species. However, there is variation around this optimum, depending on environmental perturbations. In general, if a particular resource is available in excess of normal growth requirements, the extra is shunted into making defenses (Bryant *et al.*, 1983). For example, if a plant is fertilized but retained in low light, it will shunt the extra nitrogen into nitrogen-containing defenses such as alkaloids. Of course, this occurs only in species that have the ability to make alkaloids or other nitrogen-based defenses. In contrast, if a plant is placed in a high light environment, the high rates of photosynthesis will lead to an excess of carbon in the form of starch. This extra carbon will be used to produce higher levels of carbon-based defenses such as tannins and terpenes. Note that these patterns are the opposite of the interspecific trends in which high resources select for lower defense (see Section V,D). Thus, shifts in the ratio of carbon and nitrogen available to an individual plant will cause phenotypic changes in defense allocation patterns that do not necessarily reflect the optimal trends seen across species.

Human Uses of Plant Defenses

In their daily lives, humans have long made use of plant defenses, especially plant secondary compounds. This use has been one focus of ethnobotany, which is the general study of the relationship between humans and plants. Here, we briefly review a few examples of how these plant chemicals have been employed by people. More detailed information can be found in Johns (1996).

Hunting and Fishing

Undoubtedly, one of the first uses of plant secondary compounds by humans was as poisons on the tips of arrows. As described by Neuwinger (as cited in Roberts and Wink, 1998), such poisons were formerly used with arrows throughout the world (except perhaps in Australia and New Zealand) and are still used in some areas, both in hunting and in warfare. Poisons for hunting must be highly toxic in small quantities and either easy to process during hunting trips or persistent while on arrow tips so they do not have to be replaced often. For these reasons, cardiac glycosides and alkaloids are the most common arrow poisons.

Cardiac glycosides, which are secondary compounds common in the families Asclepiadaceae and Apocynaceae, were mostly used as arrow poisons in Africa. They were often the primary active ingredient in concoctions of several different plant extracts, with the other plants added to enhance the effectiveness of the poison, to help it adhere better to the arrows, or to fulfill a magical purpose. In northern South America curare poisons were used in blowgun darts. These

were typically derived from plants in the genus *Strychnos* (Loganiaceae; also used in Africa) or from species in the Menispermaceae. Chemically, curare poisons all contain quaternary alkaloids, albeit with different structures. Once in the bloodstream, these block the transmission of neural impulses to the skeletal muscles by competing for receptors with the neurotransmitter acetylcholine. Progressive paralysis of the skeletal muscles follows, eventually leading to respiratory failure in the animal (Roberts and Wink, 1998).

In many traditional societies, poisons from plant secondary compounds have also been used in fishing. These poisons are normally put into small ponds or slow-moving streams, in which the concentration of poison will be high enough to kill or at least stun the fish. A variety of compounds have been used as fish poisons, including isoflavonoids, saponins, cardiac glycosides, alkaloids, tannins, and cyanogenic compounds. Some of the better known are flavonoids derived from the tropical legumes in the genera *Derris*, *Lonchocarpus*, *Mundulea*, and *Tephrosia*.

Medicines

As has been noted many times, the difference between a poison and a medicine is often only a matter of dosage, and this is certainly true of products from plant secondary compounds. One example is a curare poison derived from the vine *Chondrodendron tomentosum* that contains the alkaloid tubocurarine. Although it works like other curare poisons in paralyzing muscles, it was introduced to Western medicine in 1939 and is now used as a muscle relaxant in anesthesia.

It would be difficult to exaggerate the importance of plant secondary compounds in the history of medicine, both traditional and Western. It has been estimated that 25% of all prescriptions written in North America are from plant-derived drugs, and the majority of medicines in traditional cultures are derived from plants. However, only about one-half of 1% of the approximately 265,000 flowering plant species have been comprehensively evaluated for biological active compounds, the first step in determining whether a chemical can be effective as a drug. Of course, most plants do not contain medically useful compounds; therefore, an important task is to determine how to screen species in a more effective manner than simply collecting and testing plants at random. One approach, pioneered by ethnobotanists, has been to document the plants used by healers in traditional cultures. In a preliminary study, plants used by a healer in Belize produced four times as many positive results in laboratory assays than did species collected at random. A second approach is to collect plants based on ecological information. For example, as noted previously, an important defense of mature leaves in tropical forests is toughness, resulting from increased lignin and cellulose in the leaves. However, new, expanding leaves cannot be defended by toughness and so are more likely to use chemical defenses. For this reason, one way to increase the effectiveness of plant screenings for drugs may be to focus on young leaves instead of mature ones.

Regardless of the screening process, plant secondary compounds have been an important source of drugs. In particular, alkaloids have provided many noteworthy medicines in both

traditional and Western societies (Schmeller and Wink as cited in Roberts and Wink, 1998). These include atropine, codeine, colchicine, ephedrine, morphine, reserpine, taxol, and theobromine. Codeine, for example, is derived from the fruit of *Papaver somniferum* (Papaveraceae) and is a component of opium. Currently, more than 200 pharmaceuticals contain codeine, and it is used as a cough suppressant, a pain killer, and a sedative. In the West, ephedrine is used as a nasal decongestant in cold medicines and is a treatment for asthma in both Western and traditional societies. Its source is *Ephedra sinica* and *E. shunungiana* (Ephedraceae), and it works in part by raising blood pressure and respiration while causing an opening of air passages. Taxol is a recently discovered diterpene alkaloid in the tree *Taxus brevifolia* (Taxaceae) that has therapeutic use as a treatment for breast and ovarian cancer. This compound disrupts microtubule assembly in cells, making it an effective weapon against rapidly dividing tumor cells.

Self-Medication in Animals

Mounting evidence suggests that humans are not the only animals that use plant chemical defenses as medicines. Naturalists have long observed that some animals occasionally eat or rub leaves or other plant parts on themselves in an apparent attempt to cure either diseases or kill off parasites (Clayton and Wolfe, 1993). Demonstrating that this behavior is truly self-medication requires showing that the behavior is deliberate, that the plant substance used kills parasites or disease-causing organisms, and that the self-medication leads to increased fitness in the animal. Since in many cases the behavior is rare, gathering evidence to meet these criteria is difficult, but some instances are suggestive. For example, kodiak bears chew the roots of the *Ligusticum* spp. and then rub their saliva through their fur. Since this species is also used by humans as a medicine, it is possible that the bears are also using the plant to cure or ward off infections. Other vertebrates, including chimpanzees, white-faced monkeys, and birds, also use leaves of particular plant species in unusual ways or only when they are sick, suggesting that they may have medicinal value. However, it remains difficult to demonstrate conclusively that animals are truly using plant defenses as medicines.

Spices in Foods

In addition to their uses in treatment of diseases, plant secondary compounds may also be used to prevent illness. Billing and Sherman (1998) argued that people use spices in food preparation to inhibit or kill pathogenic microorganisms. They marshaled several lines of evidence to support this "antimicrobial hypothesis." First, they noted that numerous studies have demonstrated that many spices, such as onions, garlic, pepper, and chili peppers, can inhibit the growth or even kill many species of bacteria. Second, by comparing recipes of traditional cuisines from 36 countries, they found that both the proportion of recipes calling for spices and the number of spices per recipe were positively correlated with the mean annual temperature of the country. In warmer climates food should spoil more quickly, they suggested, so spices may be an important way to preserve food. Third, in warmer

countries the spices that are commonly used in cooking more strongly inhibit bacterial growth, again reflecting the greater chance of food going bad. For example, despite its strongly antimicrobial properties, garlic is not part of any traditional dishes in Norway, but it is in 80% of the recipes from Indonesia. Billing and Sherman also noted that spices are used in small quantities and thus the alternative explanation that they are used for nutritional reasons seems unlikely. Although other factors may come into play, including the greater diversity of plants in equatorial countries and the relatively slow incorporation of newly available spices into traditional cuisines, the correlations observed by Billing and Sherman strongly support their hypothesis.

Summary and Conclusions

Ultimately, the theme of this article, like that of this book, is biodiversity. Plants have evolved a stunning diversity of defenses and strategies to reduce damage by herbivores and pathogens. The most notable of these are chemical defenses, which plants use either to deter feeding (such as tannins) or to poison their natural enemies (such as nonprotein amino acids.) Plant defenses also include physical defenses such as thorns, and many species have evolved elaborate mutualistic relationships with ants, mites, and fungi as an additional means of defense. All defenses have some cost, and a defense will only be favored by natural selection if its benefits in reduced damage and higher fitness outweigh the costs of producing and maintaining the defense. Why particular species invest what they do in defenses, and why they invest in some defenses and not others, remains a subject of controversy, but there are patterns across habitats and successional series, making it clear that the evolution of plant defenses correlates with at least some abiotic factors. Finally, humans (and perhaps other animals) make use of plant defenses in their everyday lives. In food and with medicine, the lives of people have been greatly enhanced by the diverse wealth of plant

defenses. Understanding how to make a fuller, more effective use of the diversity of plant defenses found in the natural world is an important, practical goal emerging from this type of research.

Glossary

Bet-hedging strategy A trait of an organism, living in a variable environment, that leads to low variation in fitness. In general, such a trait provides an organism greater net fitness over a range of environmental conditions than would a trait specialized for any single environment. A bet-hedging trait is expected to evolve when the environment in which a species lives fluctuates over a fixed range of conditions that is sufficiently broad for fitness to vary significantly, and when precisely which state the environment will take in the immediate future is unpredictable.

Diapause A state of dormancy in some animals that is induced by a “token” environmental cue, such as day length. The token cue serves as a reliable indicator of a coming onset of harsh environmental conditions, but is not by itself harsh.

Dormancy Any state of reduced metabolic activity of an organism. Typically, dormant organisms have associated characteristics such as cessation of development, absence of reproduction, and enhanced resistance to harsh environmental conditions. Some disciplines have distinct meanings for dormancy that add further constraints to its meaning.

Egg Bank An accumulation of long-lived diapausing eggs (i.e., those eggs that persist in diapause for longer than a

single growing season) of aquatic invertebrates in the sediments of marine or freshwater habitats.

Seed Bank An accumulation of dormant plant seeds that persist in dormancy for longer than a single growing season.

Storage Effect A general mechanism for the maintenance of biodiversity within a single habitat, based on differences between competing species in their responses to environmental conditions. A resistant life-history stage can allow coexistence by the storage effect if each species reproduces successfully under the conditions favorable for that species, and can survive through unfavorable periods (e.g., when a competing species dominates) in the resistant stage. Often the resistant stage has prolonged dormancy. This mechanism can also serve to promote the maintenance of genetic diversity within a single population.

Temporal Dispersal The emergence of individuals from dormancy over a range of years (or other time interval), when those individuals entered dormancy in a single year. Often the years (or other time intervals) have different environmental qualities for growth and reproduction.

Temporal Migration The avoidance of harsh environmental conditions in an environment by an individual organism that enters dormancy before conditions become harsh and emerges from dormancy when favorable conditions return.

What are Dormancy and Diapause?

Dormancy is a very general term that encompasses a wide variety of rather different physiological states. The names applied to each of these states depend on the scientific traditions accompanying particular taxon-based disciplines. Only a flavor of this terminological diversity can be covered here, but it is important to recognize that the biological similarities (homologies) among the various physiological conditions called “dormancy” in different kinds of organisms are often questionable. In its most general sense, a dormant organism is simply one with a reduced metabolic rate. For bacteria, where life cycle and cell cycle are synonymous, dormancy is defined as a temporary loss of the ability to reproduce (Henis, 1987), though many single-celled organisms also produce hardened cases at the time of dormancy (Whitton BA, Henis Y *et al.*, and Bradbury PC in Henis, 1987). At the other end of the phylogenetic tree, vertebrate dormancy is most clearly expressed in “adaptive hypothermia” which includes both the daily torpor exhibited by a variety of small mammals and birds, and the

longer seasonal hibernation or estivation seen in many taxa (Bartholomew, 1972). These latter states are often induced in part by “token” day-length cues that initiate physiological responses (e.g., fat storage), in advance of the onset of harsh conditions. In higher plants, dormancy is divided into “seasonal” (induced by external day-length cues that foreshadow a change in season) and “opportunistic” (imposed by direct exposure to harsh conditions) categories (Harper, 1977). Similarly, in arthropods, Tauber *et al.* (1986) distinguished between “aseasonal quiescence” (“a reversible state of suppressed metabolism” rather like the “opportunistic dormancy” of plants) and “dormancy” (“a seasonally recurring period – during which growth, development, and reproduction are suppressed”). By their definition, dormancy is then further divided as “diapause-mediated dormancy” which is anticipatory, being induced by token cues (similar to “seasonal dormancy” of plants), and “nondiapause dormancy” which is essentially seasonal quiescence. The common theme here is that organisms from bacteria to vertebrates exhibit dormancy as an adaptation for survival in temporally varying

environments. Over a remarkable range of organismal complexity and phylogenetic origin, species have evolved broadly similar mechanisms for avoiding harsh conditions either by direct physiological responses to the imposition of harsh conditions, or through distinct anticipatory responses to seasonally predictable changes. These mechanisms are generally lumped under the broad umbrella of “dormancy.”

Depending on the organism and the environment in which it resides, the duration of dormancy or diapause can be brief or can last for extraordinary periods of time. For microbial cysts, dormant seeds, and diapausing eggs, there are reports of remarkable abilities to survive for centuries in dormancy: There are examples of bacteria becoming active after 200 years, of plant seeds germinating after thousands of years, and of crustacean eggs hatching after 300 years (for a review, see [Hairston et al., 1996](#)). The diapausing eggs of *Artemia* (fairy shrimp from salt pans along San Francisco Bay) can survive more than 4 years of complete anoxia with no measurable amounts of stored carbohydrates used during this period, and no detectable metabolic rate, even down to 1/50,000th of the aerobic respiration rate ([Clegg and Jackson in Brendonck et al., \(1998\)](#)). Thus, at least some organisms can apparently survive as “living dead” – that is, in a state without detectable metabolism but still capable of becoming active when exposed to favorable environmental conditions.

Dormancy can occur at many points in an organism’s life cycle, from embryo to juvenile and adult stages, depending on the species. Indeed, for some organisms, dormancy may occur at several different life history stages in a single population. Perennial plants may express both bud and seed dormancies ([Harper, 1977](#)). Some invertebrates, such as cyclopoid copepods, can enter diapause at several different stages ranging from immatures to adults ([Elgmork K in Alekseev and Fryer, 1996](#)) and even as fertilized females ([Alekseev and Fryer, 1996](#)). Some fishes can estivate as adults, whereas others, such as the annual killifishes make diapausing eggs capable of surviving several years in desiccation. Some mammals can exhibit both adult hibernation and delayed implantation, a kind of embryonic diapause. In general, short-term dormancy (from a few weeks to a few years) is characteristic of species that are dormant as immature individuals or adults, whereas long-term dormancy (years to centuries) is only found in species that possess embryonic (i.e., seed or egg) dormancy. However, many seeds and eggs actually remain dormant for only brief time periods.

Dormancy and Diapause as Adaptive Traits

It is axiomatic that if individuals that possess dormancy within a population survive a harsh period whereas others that lack dormancy do not survive, then genotypes expressing dormancy will be favored by natural selection. It is less obvious, however, precisely where the tradeoff lies if the harsh environment is not fatal to nondormant individuals. Dormancy represents a reproductive delay (i.e., a lengthening of generation time), and therefore a reduction in potential rate of population increase. [Cohen \(1970\)](#), modeling insect diapause, showed that all individuals in a population should enter dormancy when the arithmetic mean of potential

reproduction in the active stage drops below the harmonic mean of survival in the dormant stage. The “means” in Cohen’s analysis represent long-term probabilities of successful reproduction or survival. Likewise, [Cohen \(1966\)](#), this time taking plant seed dormancy as his inspiration, showed that the optimal fraction of seeds germinating in any given year depends on the probability that an individual will contribute to long-term fitness through reproduction as a growing plant compared with the contribution it would make by simply surviving another season as a dormant seed. Cohen’s important contribution in these two papers was to show that dormancy is not only a response to the certain extermination of active individuals in a highly seasonal environment, but also that it is expected to evolve as a response to environmental uncertainty. It is because not all harsh periods are fatal, and not all growing seasons are bountiful that variation in the expression of dormancy exists both within and among species.

Variation in Dormancy and Diapause

There is often variation within a group of species living in a single environment either in whether or not any given species makes dormant eggs or seeds, or in the time of year that these dormant stages are produced (see [Harper, 1977](#) for examples in plants, and [Tauber et al., 1986](#) for examples in insect diapause). This may be expected if different species react to the environment in different ways. One species may perceive a change as highly unfavorable to which another is relatively immune. There are many examples of populations in which only a fraction of individuals enter dormancy ([Venable DL in Leck et al., 1989](#); [Tauber et al., 1986](#)). In these cases, it seems likely that a kind of “bet-hedging” strategy has evolved in response to variation through time, typically among years. In the models reviewed, whether dormancy is favored or not depends on the relative expectations of growth and reproduction in the active stage and survival in the dormant stage. If these expectations vary substantially over time, then the most successful phenotype may be one in which some individuals remain active (in case conditions remain favorable) and others enter dormancy (in case conditions become too harsh). For the same reason, there may be variation in the time of year that individuals within a population enter dormancy or diapause: In some years, the seasonal onset of harsh conditions comes early and in other years, the onset comes later. An example of this variation is a population of freshwater crustaceans (the calanoid copepod, *Diaptomus sanguineus*, living in a small lake in Rhode Island) in which one subpopulation switches from making eggs that hatch immediately to making diapausing eggs significantly earlier in the season than the second subpopulation ([Ellner SP et al., in Brendonck et al., \(1998\)](#)).

Time Travelers: Dormancy and Diapause as “Migration from the Past”

Many organisms migrate seasonally away from environments that become uninhabitable at one time of year (usually winter). These include both vertebrates (birds, mammals, and fish)

and invertebrates (e.g., some butterfly and lobster species). There is a large group of organisms, however, that are unable to undertake long-distance movement, and so must survive the seasonally harsh environments where they live. Microbes, fungi, plants, and a great many invertebrates have this life history constraint, as do some vertebrates that hibernate rather than migrating. In a very real sense, the organisms that cannot migrate spatially have evolved dormancy as a kind of temporal migration from one favorable season to the next. Migration is a directed movement between spatially separated habitats. Dormancy is especially analogous to migration when an organism not only begins dormancy before conditions become harsh, but also emerges only when conditions become favorable again. For plant seeds, this is known as "predictive germination" (Venable DL in *Leck et al.*, 1989), but many other types of dormancy termination have a predictive character, such as spring arousal from hibernation in mammals or the hatching of crustacean diapausing eggs only when their temporary pond habitat refills with water.

Also analogous to migration are spatial and temporal dispersal in unpredictably varying environments. Spatial dispersal contrasts with migration in that it is a nondirectional movement of individuals away from a source population. It is often interpreted as an adaptation for survival when habitat patches become uninhabitable asynchronously. An individual that produces many offspring, each of which disperses to a new habitat, plays a kind of probabilistic game with many young landing in unfavorable habitats where they die, but with at least some landing in sites where they can successfully grow and reproduce. For organisms lacking effective spatial dispersal in an environment that is unpredictable through time, prolonged dormancy is an effective alternative mechanism for continuing success. An individual that produces many dormant seeds, cysts, or eggs, each of which is capable of surviving long periods of time (i.e., over what would be multiple generations or seasons in the active life history stage) before germinating or hatching, exhibits a kind of temporal dispersal. This is true in particular if the dormant propagules also distribute their emergence from dormancy over multiple seasons. Then, as in spatial dispersal, the dormant offspring awaken in a range of different conditions. Many will emerge at times when the habitat is harsh, but some will emerge and have successful growth and reproduction, producing new long-lived dormant propagules. Seeds with prolonged dormancy are said to belong to a "seed bank" (*Leck et al.*, 1989), and eggs in prolonged diapause are, by analogy, said to belong to an "egg bank" (*Hairston et al.*, 1996).

Spatial dispersal and prolonged dormancy are predicted in theory to be alternative life-history adaptations (*Hairston NG and McPeck M and Kalisz S in Brendonck et al.*, 1998). Organisms that have excellent spatial dispersal capabilities should not experience strong selection for long-term survival in dormancy, and *vice versa*: Organisms with effective prolonged dormancy should not also evolve mechanisms for spatial dispersal (*Cohen D and Levin SA*, 1987). Consistent with this theory, there are significant negative relationships between spatial dispersal ability and seed dormancy in plants (*Venable DL in Leck et al.* 1989; *Rees*, 1993). Similar considerations may explain why winged insects, although often

exhibiting single-season diapause (*Tauber et al.*, 1986), very rarely possess diapause that extends over longer periods.

For a variety of species that make dormant propagules (i.e., either dormant seeds or diapausing eggs), there is evidence that these stages can facilitate both spatial and temporal dispersal. The resistant stages that permit dormant organisms to survive stressful periods *in situ* also make it possible for them to withstand unfavorable conditions during transport, whether by physical forces such as wind or water currents, or as hitch-hikers attached to more mobile animals. There is evidence, however, that tradeoffs still exist in which function is most important for a given organism: Plant species with elaborations attached to their seeds that promote wind dispersal have shorter-term dormancy than those that lack such structures (*Rees*, 1993).

Limitations inherent in spatial dispersal for invertebrates living in lakes and other inland pools very likely explain why diapause and dormancy are so much more prevalent among taxa living in this habitat than in related animals found in marine environments where ocean currents provide for passive dispersal. In a survey of 167 species of crustaceans, *Hairston and Cáceres (in Alekseev and Fryer, 1996)* found that greater than 55% of those living in inland water bodies possessed a long-lived diapausing stage, whereas less than 10% of marine species possessed this trait. More broadly, prolonged dormancy occurs much more frequently in invertebrate phyla with species that occur in nonmarine habitats than in invertebrate phyla that are exclusively marine. Indeed, no exclusively marine phylum, and only one of 28 exclusively marine classes is known to exhibit prolonged dormancy (*Cáceres, 1997a*). Several studies have suggested that possession of prolonged dormancy or diapause may facilitate invasion of inland waters by aquatic invertebrates (*Hairston NG and Cáceres CE in Alekseev and Fryer, 1996; Cáceres, 1997a; Hairston and Bohonak, 1998*). Furthermore, those taxa that have persisted the longest in freshwater habitats, over geological time, are the ones with prolonged diapause (*Alekseev and Starobogatov YI in Alekseev and Fryer, 1996*).

The Storage Effect, Prolonged Dormancy and Diapause, and the Maintenance of Biodiversity

Long-lived dormant stages that spread their germination or hatching over an extended period of time can play a major role in maintaining both the coexistence of species within a community, and of genotypes within a population. This is especially true when the environment varies through time with some species (or genotypes) favored under some environmental conditions and others favored under other conditions. As an example, consider two competing plant species for which the environment varies through time so that each species has years in which it does well and others in which it does poorly. Also, suppose that in those years when one species does well, the other does poorly. In the absence of seeds with prolonged dormancy, one species would be expected to be competitively superior on average, and thus to eliminate the other over time. However, if both species have long-lived seeds, then the one that is on average the poorer performer can persist by producing seeds when conditions are favorable and

survive in dormancy through years of poor growth and reproduction. This scenario can be extended to communities of many species: If for each species there is an environmental condition in which it does better than its competitors, and if each has some seeds that germinate in each year, then all species can take advantage of years favorable to their own growth and reproduction while not suffering serious fitness loss in years that are unfavorable. Theoretical studies have shown that many species can coexist by this scenario, which is one example of a more general mechanism called the "storage effect" (Chesson, 1994). Its importance in natural communities has been demonstrated for two species of competing freshwater crustaceans in the genus *Daphnia* that make long-lived diapausing eggs (Cáceres, 1997b), and for desert annual plants with long-lived seeds (e.g., Philippi TE in Brendonck *et al.*, 1998).

A similar process can maintain biodiversity of genotypes within a single species if individuals with different genotypes perform best in years of differing environmental quality (Hairston *et al.*, 1996). The major difference between the theory for species competing within a community and that for genotypes competing within a population is evolution. In a community of competing species, one needs only to ask if those species present can coexist. With evolution, however, it is theoretically possible for natural selection to produce a single genotype that has a greater long-term fitness than any other genotype. The question now becomes whether other genotypes with lower long-term fitnesses can coexist in the presence of this most-fit type. The answer is "no" if dormancy is absent or only short term, but "yes" if dormant stages are sufficiently long lived and if natural selection fluctuates sufficiently to favor different genotypes at different times (Hairston *et al.*, 1996). This has been shown to be the case for a population of freshwater crustacean copepods, *D. sanguineus*, with long-lived diapausing eggs, that experience fluctuating natural selection due to year-to-year changes in fish predation pressure (Ellner *et al.*, 1999), and for the freshwater cladoceran *Daphnia magna*, which experiences antagonistic coevolution with the bacterial parasite *Pasteuria ramosa* DeCaestecker *et al.*, (2007).

The characteristics of organisms and their environments that make it likely that dormancy plays an important role in maintaining biodiversity are (1) an environment that fluctuates through conditions that favor a diversity of types of organisms and (2) dormancy or diapause of sufficient duration to span the time it takes for favorable conditions to recur for each organism type. A literature review on these topics by Hairston *et al.* (1996) shows that both of these conditions are quite common in nature for a wide variety of taxa and habitats.

Through its influence on genetic diversity, dormancy or diapause can influence the evolutionary potential of populations. As genotypes from different generations accumulate in the dormant propagule bank, fluctuating or variable selection as described above (in this section) can lead to greater variance of traits compared with the active population, whereas directional selection can cause the mean genotype of the dormant stages to be quite different from that in the active population (Levin, 1990; Hairston *et al.*, 1996). Depending on the dynamics of hatching and viability, the greater genetic

variation of this pool can lead to more rapid evolution (Levin, 1990) or to retarded rates as "old" genotypes continue to reappear (Templeton and Levin, 1979). For example, Hairston and Destasio (1988) demonstrated that the dormant egg bank of the copepod *D. sanguineus* slowed down the rate of change in the timing of diapause egg production.

Summary

Dormancy is a term that covers a variety of physiological states in a wide range of kinds of organisms. In each of its forms, dormancy plays a role in the ability of species to live where they do, and is thus important in explaining what organisms are found in which environments. The presence of prolonged dormancy as a character in a taxonomic group of organisms can be critical to the ability of that group to invade and colonize new habitats. This is particularly true for habitats that vary greatly through time and for groups with restricted abilities to disperse spatially. Finally, prolonged dormancy, when combined with a temporally varying environment, can be a significant factor in maintaining both genetic and community biodiversity within a habitat.

Introduction

Eukaryotes are cells commonly identified by the presence of a nucleus. Eukaryota is one of the three domains of life (bacteria and archaea are the others and collectively referred to as prokaryotes) and encompasses single-celled organisms as well as all multicellular life. The evolution of eukaryotes is rather unique because it is substantially non-Darwinian; where Darwinian evolution largely concerns itself with beneficial genes arising by mutation and then spreading through differential reproductive success, the story of eukaryotes is one of significant horizontal gene flow (the exchange of genes across species) and of distinct organisms fusing into entirely new organisms.

Eukaryotes contain a variety of structures that distinguish them from prokaryotes (archaea and bacteria), most notably the nucleus and a host of organelles (endoplasmic reticulum, Golgi bodies, peroxisomes, mitochondria, chloroplasts, etc.). They also possess flagella of unique structure (containing microtubules) and cytoskeletal structures made of microtubules and microfilaments (neither of which is found in prokaryotes). Eukaryotes also often organize their DNA around histones (proteins that act like spools) and package it into chromosomes. Some eukaryotes also participate in some form of sexual reproduction though many retain the ability to reproduce asexually.

Timing of the emergence of earliest eukaryotes is greatly debated. The first evidence of eukaryotes puts their origin at about 2.3–1.6 billion years ago. This range is derived primarily from phylogenetic analyses. Multicellular algae fossils are dated at 1.2 billion years, thus providing an absolute lower bound while fossils of single-celled organisms resembling algae are dated to around 2.2 billion years old, though scientists debate whether these represent eukaryotes or are merely similar in appearance.

Most calculations place the oldest eukaryotes close to the first global glaciation approximately 2.3 billion years ago. It is believed that a rise in the number in photosynthetic prokaryotes led to an increase in oxygen, which resulted in global cooling. This increase in oxygen is believed to have decimated populations of anaerobic prokaryotes. Some scientists believe that eukaryotes existed in low abundance before the rise in oxygen while others believe they originated shortly after. Scientists do agree however that the rise in oxygen is likely responsible for their increase in abundance and rise to multicellularity.

It is important to note that much of the theories regarding the origins of eukaryotes are speculative and it is unlikely that any one hypothesis will ever be championed above all others. However, as we sequence more genomes (particularly those of proposed early eukaryotes, and complete genome sequences

of organisms from all domains of life) and develop more sophisticated phylogenetic techniques, it will be possible to narrow the likely possibilities.

Eukaryotes as Chimera

Eukaryotes are chimeric in that their DNA is the fusion of more than one genome. Phylogenetic analyses of eukaryotic genes result in many conflicting results, some eukaryotic genes appear most recently derived from archaea, while others from bacteria. If these conflicts were infrequent, horizontal gene flow could be an adequate explanation. However, these conflicts are frequent and appear to fall into distinct categories. Genes involved in the maintenance and manipulation of the genetic code appear to be most recently derived from archaea, whereas genes that are involved in metabolic processes are most similar to those of bacteria. Thus, it appears that at least two organisms are responsible for the major contributions to the eukaryotic genome and thus any theory on the evolution of eukaryotes must be one that can account for this pattern.

Curiously, genes believed to be of bacterial origin are sometimes grouped most closely with Gram-negative bacteria (like *Rickettsia*), while others are grouped most closely with Gram-positive bacteria (suggesting at least three major contributors). Debate exists however concerning whether these two groups are each monophyletic (consisting of a common ancestor and its descendants).

The Archezoa were (as many of these organisms are now being placed elsewhere) a group containing various eukaryotes that lacked mitochondria (amitochondriates) and often lacked or possessed 'primitive' versions of some eukaryotic traits. They are largely parasitic, inhabiting low oxygen environments, and were believed to descend from an ancient eukaryote before the acquisition of mitochondria. Recent phylogenetic analyses however have shown that many of these species are relatively recent with highly simplified structures resulting from their parasitism and anoxic environments. Structures similar to mitochondria have been found in many (though they may lack DNA) as well as nuclear genes normally associated with mitochondrial DNA.

Before the demise of Archezoa scientists had a rather gradual interpretation of eukaryotic evolution from simple cells to more complicated eukaryotes gradually with eukaryotic lineages diverging along the way acting as living fossils of earlier versions. With recent discoveries however, scientists are now of the opinion that most of the major features of eukaryotes (nucleus, cytoskeleton, ability to endocytose, and mitochondria) evolved very rapidly. It is now believed that if any early diverging lineages existed, they are now extinct and did not contribute to modern lineages.

No matter the theories concerning the origin of eukaryotes, there are hypotheses that can account for their chimeric nature. Woese has proposed that early in the evolution of eukaryotes horizontal gene flow was much more common, and as genomes became more complex and integrated these rates decreased. Doolittle posits that the advent of the cytoskeleton and ability to phagocytose gave eukaryotes the potential to incorporate DNA from ingested organisms. Over time, numerous organisms contributed to the genome of early eukaryotes. While it is difficult to test either of these hypotheses, if future comprehensive phylogenetic analyses across a great many organisms point to 'few' donors for the origin of eukaryotes, then these ideas would be disproved.

Origin of Eukaryotes

An important feature of eukaryotes when discussing their evolution is that they are believed to have originally lacked cell walls or a rigid membrane as found in most prokaryotes. These early eukaryotes would have needed some kind of cytoskeleton to maintain integrity and shape. Cytoskeletal elements are also involved in eukaryotic reproduction, mobility, and the ability to endocytose. Curiously, no solid evidence exists for the evolution of the cytoskeleton from some prokaryotic precursor (though actin and tubulin have weak similarity to archeon proteins). Thus, it seems likely that the cytoskeleton evolved largely *de novo* within the early eukaryote and also that many of the structural and functional characteristics of modern eukaryotes were possibly present in some of the earliest eukaryotes. Reasons for the loss of a cell wall are unclear though it may have been in response to bacteria-secreted antibiotics that often target cell walls.

Probably the simplest theory for the origin of eukaryotes is that the proto-eukaryote diverged from an archeon and that it later derived its bacterial characteristics from its proto-mitochondrial symbiote; however, another popular theory holds that a bacteria and archaea genomes fused prior to the acquisition of the mitochondrion ancestor. In these scenarios it is unclear whether the early eukaryote possessed a nucleus before the mitochondrial event or whether it developed afterwards. Some hypothesize that the nucleus must have been in place prior to prevent harmful genetic interactions with the proto-mitochondria genome, others that the nucleus evolved in response to the acquisition.

Other theories hold that the nucleus is the result of a host bacteria fusing with an archeon or virus (something resembling mimiviruses which have rather large genomes and are less dependent on their hosts cellular machinery; referred to as viral eukaryogenesis). In some versions the bacterial host is RNA-based and the genes controlling the manipulation of genetic code were replaced by those of the DNA-based archeon or virus, leaving the other cellular machinery bacterial.

Figure 1 shows the four major competing theories for the origin of early eukaryotes resulting from ambiguity of two major events. First, have they diverged from an archeon or are they the result of a fusion between an archeon and a bacterium, and second, did eukaryotes exist in an amitochondriate phase during their evolution?

The 'hydrogen hypothesis' proposed by Martin and Muller holds that a methanogen archeon (which metabolizes hydrogen and carbon dioxide and releases methane) endocytosed the future mitochondria and that it provided the host cell with hydrogen and carbon dioxide as by-products of anaerobic respiration. This idea was inspired by hydrogenosomes which are simplified mitochondria often found in anaerobic eukaryotes and are believed to have evolved independently multiple times.

Lynn Margulis has proposed that eukaryotes originated when an archeon developed an ectosymbiotic relationship with a spirochete (a type of bacteria) and eventually their genomes fused; this places an exogenous origin for the flagellum and occurs before acquiring a bacterial endosymbiont. This idea was inspired when observing that some eukaryotes rely on symbiotic spirochetes for their motility (parabasalids within the termite gut). This theory has many bacteria-like genes originating from the spirochete and not the later mitochondria. However given that there is little similarity between spirochetes and eukaryotic flagella, this theory is currently rather unpopular.

Endosymbionts

Two of the more observable organelles in eukaryotes are mitochondria and plastids (plastids which contain chlorophyll *a* and *b* are chloroplasts). Mitochondria are often referred to as cellular 'power plants' and are responsible for oxidative phosphorylation; this enables aerobic respiration (which yields 15 times as much ATP from glucose than does anaerobic respiration alone), while chloroplasts allow for photosynthesis. The acquisition of these organelles would clearly have been an energetic boon to the eukaryotes possessing them.

Unlike theories on the origins of the eukaryotes, the 'endosymbiotic theory' has remained relatively unchanged for decades, has a host of strong evidence, and is almost universally accepted. The endosymbiotic theory dates back to 1883 when Andreas Schimper observed that chloroplasts divided similar to cyanobacteria (blue-green algae which are bacteria despite their common name). In 1905 Konstantin Mereschkowsky suggested that plastids were originally endosymbionts (beneficial organisms living within another organism), and in the 1920s, Ivan Wallin suggested the same for mitochondria. These ideas were based on visual similarity when viewed under light microscopy and were largely ridiculed until the later half of the 1960s, after which Lynn Margulis helped popularize the 'endosymbiotic theory' in her book *Origin of Eukaryotic Cells* (1970).

The 'endosymbiotic theory' states that mitochondria and plastids evolved from an engulfed bacteria and cyanobacteria, respectively. It is believed that a host cell engulfed an anaerobic bacterium (perhaps as prey or a parasite) and that over time a symbiosis arose, eventually becoming an obligate symbiosis (a mutually beneficial interaction required by both participants) before evolving into mitochondria. Later a mitochondria-harboring host engulfed a cyanobacterium, which similarly evolved into plastids. The mitochondrial event is believed to have occurred near the origin of eukaryotes

themselves, and the plastid event about a half billion years later.

Evidence

Much of the evidence for the endosymbiotic theory comes from the structure and handling of these organelles' genetic codes. Both mitochondria and plastids have DNA sequences in circles as that of bacteria. Their DNA also lacks histones (proteins that the DNA is wrapped around) which are present in eukaryotes and some archaea. In addition, mitochondria and plastid transcription begin with the amino acid fMet (formylmethionine) as in bacteria, not Met (methionine) as in eukaryotes.

Ribosome sizes are questionable evidence for the endosymbiotic theory. Bacteria usually have ribosomes of 70s (Svedberg units) and eukaryotes usually have around 80s in their cytoplasm. While the mitochondrial and plastid

ribosomes are usually of around 70s, they do in fact vary among species from around 60s to 80s, thus overlapping both bacterial and cytoplasmic eukaryote ribosome sizes.

Other evidence for the endosymbiotic theory comes from the two membranes usually surrounding these organelles. The inner membrane belongs to that of the original bacteria and outer membrane presumably a result from the original engulfment. The outer membrane has approximately a 1:1 protein–lipid ratio by dry weight, similar to many eukaryotic cytoplasmic membranes, while the inner membrane (which is made of two layers) has approximately a 3:1, similar to many bacteria. These organelles and bacteria also both utilize electron transport enzymes lacking elsewhere in eukaryotes.

Some of the best evidence for the endosymbiotic theory however comes from bioinformatics. Phylogenetic analyses of various bacteria, mitochondria from various hosts from various kingdoms, and nuclear DNA from those hosts usually place mitochondria as most related to a group of bacteria known as proteobacteria, often placed closest to *Rickettsia*

and other α -proteobacteria. The α -proteobacteria as a group are almost entirely symbiotic or parasitic which may have predisposed the mitochondrial ancestor to an existence within its host. Chloroplasts are most often placed next to cyanobacteria and both contain thylakoids and chlorophyll *a*; cyanobacteria are also involved in a number of symbioses including lichens and corals.

Problems

Some inconsistencies do exist between bacteria and plastids/mitochondria. Mitochondria possess the ability to fuse with other mitochondria (this is believed to be the result of simplification that has occurred within the mitochondrial membranes over time) and the genetic information within a mitochondrion or plastid also differs in some ways to that of bacteria. These organelles possess higher concentrations of introns (DNA that will be spliced out prior to translation) than bacteria and intron types not found in bacteria. The genomes of these organelles are also much smaller than those of bacteria.

Gene flow between the nucleus and the organelles is believed to be responsible for the genetic discrepancies. Gene flow from the nucleus to an organelle first requires a copy of a segment of DNA from the organelle to insert into the nuclear DNA and gain expression. Loss of function can then occur in the original gene. A similar process can explain migration from the nucleus to the organelles. While organelle DNA fragments within nuclear DNA are rather common, nuclear DNA fragments within organelle DNA are rare (the exception being plant mitochondria which has experienced a rather large increase in genome size over time). Such genetic transfers operate with a frequency similar to that of mutation.

The introns within the organelles and the increase in the plant mitochondria genome over time are thought to be due to a transfer from the nucleus to the organelles. The size discrepancy between the genome sizes of chloroplasts and mitochondria is believed to be a result of selection for genes originally possessed by the organelles to reside in the nucleus.

Selection for the migration of genes to the nucleus comes in many possible forms. First, it is believed to be physically more difficult for DNA to enter these organelles as compared to the nucleus. Population genetics also tells us that sexual reproduction (which many eukaryotes possess) enables the more rapid spread of advantageous genes, and overcomes Muller's ratchet (the idea that asexual reproduction lacks an effective means of ridding the genome of deleterious mutations that gradually build up). Also, chloroplasts and mitochondria perform redox (reduction–oxidation) reactions, which are prone to producing deleterious mutations. Finally, it has been proposed that smaller organelle genomes would replicate faster than those with redundant genes and thus be selected for.

The reasons for maintenance of organelle DNA are not as clear. Some reasons might include, that the remaining genes code for proteins that cannot be easily transported into the organelle (possibly membrane-spanning or strongly hydrophobic proteins) or that these genes are harmful if expressed in the cytoplasm. Another potential reason may be the slight differences in organelle versus nuclear transcription/translation.

Secondary Endocytosis of Plastids

Green algae and plants are believed to be descendents of the original plastid-harboring eukaryote. However, some protists contain plastids that are believed to be from other eukaryotes. These protists have within their endoplasmic reticulum an endosymbiont resembling a eukaryote. This endosymbiont possesses its own plasma membrane and ribosomes (which are both similar to those of eukaryotes) as well as the remnant of a nucleus containing its own DNA (a nucleomorph), and finally plastids. Thus, these organisms have four sets of DNA: mitochondrial, plastid, nuclear, and nucleomorph. Some protists may even contain plastids from tertiary endocytosis.

Other Possible Symbiotic Events

Christian de Duve proposed that peroxisomes (which contain enzymes for oxidative reactions) may also have originated as endosymbionts; however, because of their single layer membranes, lack of DNA, and the recent observation that peroxisomes can be formed from the endoplasmic reticulum, it is now generally accepted that they arose endogenously.

Lynn Margulis proposed in 1967 that along with mitochondria and plastids, the eukaryotic flagella was also the result of symbiosis (*see* Origin of Eukaryotes). However, this fell largely out of favor when flagella were found not to possess DNA, and subsequently that spirochetes are rather dissimilar to eukaryotic flagella.

Glossary

Adaptation Characteristics of an organism that suit it to its conditions of existence, accounting for the similarity of organisms leading the same way of life; under the theory of descent with modification, a derived feature of an organism that increases the survival and reproduction of the organism by virtue of the possession of that feature.

Anagenesis Evolutionary changes occurring within an ancestor–descendant lineage.

Cladogenesis Splitting of a lineage into two or more descendant lineages.

Natural selection Consistent differential survival and reproduction of heritable variants.

Phylogenetic tree A tree-like diagrammatic representation of ancestry and descent and the branching of lineages; Darwin thought a coral might be more apt, but in either case, the form represents the actual physical continuity of the transmission of materials and information from one generation to the next.

Unity of type Similarities among organisms leading diverse ways of life under diverse conditions of existence, going beyond any functional need for similarity; under the theory of descent with modification, these similarities result from common ancestry.

Introduction

What a Theory is

Before embarking on an exposition of the theory of evolution, it is necessary to clear up a common misunderstanding that arises from a confusion of the vernacular and technical meanings of the word “theory.” In everyday speech, “theory” is often taken to mean a guess, an hypothesis, or a speculation – something opposed to the more surely known “facts.” In the context in which the word is used in the phrase “evolutionary theory,” however, and indeed in much of science, it signifies a series of interconnected high-level generalizations based on a large body of evidence. Thus, one speaks of “atomic theory,” “quantum theory,” or the “germ theory of disease.” Far from indicating that these sets of connected propositions are mere speculations, it indicates that they are well supported by a considerable corpus of data.

All scientific theories, of course, are provisional (as indeed are all scientific “facts”) and subject to revision in the light of further data. It is always salutary to bear this in mind, and also that some of the ideas and findings are more likely to be subject to revision than others. But it is important to know that the word “theory” does not partition scientific propositions into those more or less likely to be revised. Rather, it attaches to some of the most well-supported propositions, as in the examples just discussed. It is in this sense that this article refers to the “theory of evolution.”

What Evolution is

If “evolution” means “change over time,” there are many things that evolve. Solar systems, for example, evolve. Stars condense, planets form, comets come and go, and stars age in predictable sequences. Languages also evolve. Within

historical times, Latin has given rise to French, Spanish, Italian, and the other Romance languages, while contributing much vocabulary to the development of English. But the biological theory of evolution does not encompass cosmology or historical linguistics; rather it is restricted to organic evolution, that is, changes in living beings over time. This formulation is still too broad, since individual organisms grow and develop over time (i.e., have an ontogeny), but this is not evolution in the modern sense. The changes in life over time that concern humans are those that persist beyond the lifetime of a single individual and are transmissible to offspring (i.e., are heritable). So organic evolution consists of changes in living beings that transcend a single generation, and which, in principle, can be transmitted through an indefinite number of generations.

The theory of evolution, as considered here, is primarily concerned with the mechanisms of evolutionary change. The study of evolutionary mechanisms, or the causes of evolution, however, is but one of the two great branches of evolutionary biology (Futuyma, 1998). The other is the study of the history of life – phylogeny in the broad sense. The biodiversity observed today, and in the fossil record of past times, is the product of evolutionary mechanisms in tandem with changes in environment and geography acting on organic beings over long periods of time. This history of life and its present condition and causes, of both particular branches of the phylogenetic tree and biodiversity in general, are the subject of the greater part of this Encyclopedia.

Genetics, ecology, and developmental biology are among the disciplines that contribute largely to the study of evolutionary processes, whereas systematics and paleontology are among those that contribute to evolutionary history and the estimation of the evolutionary chronicle (O’Hara, 1988). All these disciplines, however, interact in ways that do not allow a neat separation of their contributions to the two sides of

evolutionary biology. As Dobzhansky (1973) noted, nothing in biology makes sense unless it is studied in an evolutionary context, and all fields of biology provide insight into the processes of evolution and the history of life.

Brief History of Evolutionary Thought

Prior to Darwin

Charles Darwin (1809–1882) is the central figure in the development of evolutionary biology (Browne, 1995, 2002), with the publication of *On the Origin of Species* in 1859 being especially crucial (Browne, 2007). It is convenient to consider the state of biological thought before and after his contributions.

Prior to Darwin's work, a number of fundamental building blocks for evolutionary biology had been established. Chief among these were conclusions from Earth sciences: Earth was old (although no reliably exact estimate was made till well after Darwin's death), some ancient forms of life had become extinct, and the fossil record of life on Earth was progressive (i.e., the various forms of life existing at different times differed from time to time, and younger fossils more closely resembled the modern biota) (Young, 2007). These facts showed that life had a long history, but did not establish the causes of that history, nor what the connections were, if any, between the successive life forms.

A number of speculations were made that are now termed "evolutionary" (at the time, "evolution," from a Latin root meaning unfolding, was applied most often to ontogeny), but the first prominent and consistent scientific evolutionist was Jean-Baptiste Lamarck (1744–1829). Lamarck proposed that species originated continually via independent events of spontaneous generation and subsequently progressed "up" the scale of nature, from less complex to more highly organized beings. He viewed this as an inherent attribute of living things. As a subsidiary mechanism of transformation, and, in particular, of branching of forms from the inherent upward path,

he supposed that the effects of individual striving and activity in response to the environment could be passed on, resulting in adaptation to the conditions of existence. The inheritance of acquired characteristics was thus a secondary mechanism for Lamarck (as, indeed, it would be for Darwin). Lamarck did not succeed in convincing many of his contemporaries; luminaries such as the paleontologist Georges Cuvier (1769–1832) and geologist Charles Lyell (1797–1875), who otherwise disagreed on many issues of Earth's history, nonetheless agreed in their condemnation of Lamarck's "transformism" (Corsi, 2005) and insisted on the fixity of species (Figure 1).

Another key building block of evolutionary biology was the recognition of the great diversity of life and its geographic distribution, with new and distinctive forms from around the world flooding the museums of Europe in the late eighteenth and early nineteenth centuries. The botanist Carolus Linnaeus (1707–1778), through his system of nomenclature, provided a common language for discussing this diversity, but it did not imply any genealogical connectedness among the forms so classified.

Darwin

In the first part of the nineteenth century, the two key problems facing biology were unity of type and adaptation. "Unity of type" referred to the similarities of organisms that led different – and sometimes very different – ways of life. All tetrapods, whether they be flying birds, walking turtles, grasping monkeys, or swimming ichthyosaurs, have a forelimb composed of a proximal humerus, then the radius and ulna, then the wrist and palm bones, and finally the phalanges – a pattern of "one bone, two bones, many bones" repeated throughout the amphibians, reptiles, birds, and mammals (Shubin, 2008). These bones vary in size, shape, and sometimes in number, but the generality of the pattern is striking. Similarly, vertebrate embryos of particular stages are strikingly alike, even though the adults differ starkly, leading the embryologist Karl Ernst von Baer (1792–1876) to formulate his

Figure 1 Proposed trees of ancestor–descendant relationships visualized by Lamarck (a) and Darwin (b). (a) Lamarck proposed that organisms originated spontaneously and continuously and evolved "up" a chain of natural being. (b) Darwin proposed that all species evolved from a common ancestor through the mechanism of natural selection. Reproduced from Futuyma DJ (1998) *Evolutionary Biology*, 3rd edn. Sunderland, MA: Sinauer.

law that, within a group, development proceeds from a common plan and progressively diverges, so that a pig embryo can be recognized to be that of a vertebrate early in development, but acquires the distinctive features of mammals later, and those of pigs later still.

“Adaptation” referred to the suitability of organisms to the conditions of existence – the fit of the organism to the environment. A hummingbird, which feeds on the nectar of flowers with long corollas, is thus suited to its conditions of existence by the possession of a long bill and tongue. A bananaquit, which feeds on nectar by snipping into the base of a flower, is suited to its conditions of existence by possessing a short, sharp bill. The birds’ bills fit them to their conditions of existence and are thus adaptations to the conditions of existence.

In similar environments, similar adaptations may be found, even though the organisms exhibiting them are otherwise quite different. Thus, dolphins, ichthyosaurs, and sharks all possess a streamlined shape, dorsal fins, compressed tails, and steering forelimbs, yet one is a mammal, one a reptile, and one a fish, which differ from one another in their circulatory, respiratory, reproductive, and other systems in striking ways, despite their close similarity of overall appearance due to features that suit them to their conditions of existence.

The genius of Darwin was to propose a unified explanation for both unity of type and adaptation: descent with modification. Descent implied the well-known phenomenon of parent-to-offspring inheritance, whereas modification provided for changes from generation to generation. Unity of type was thus explained by descent from common ancestors: the resemblances of general body plan of organisms living diverse ways of life are due to the inheritance of the shared features from a common ancestor. Inheritance was understood in general (although not in its details until after Darwin), but what was most needed was a mechanism of modification and, furthermore, a mechanism that could account for adaptation. The need for an explanation of adaptation was especially felt in Britain, where the tradition of natural theology, exemplified in the work of William Paley (1743–1805), held that the often remarkable and complex fit between organisms and their conditions of existence was evidence of divine providence. The mechanism of modification that could account for adaptation proposed by Darwin (and also independently by his great collaborator Alfred Russel Wallace, 1823–1913) was natural selection, which he regarded as the chief, though not the only, means of modification.

Because many (though not all) of Darwin’s proposals have been borne out and expanded by modern evolutionary biology, details of some of these proposals will be presented in the section Darwin’s Five Theories.

The Modern Synthesis

Although Darwin rapidly succeeded in convincing the scientific community of the truth of descent with modification, acceptance of his view that the chief mechanism of modification (and the one most sure to produce adaptation) was natural selection acting on variation within populations was

much delayed. Acceptance of the latter proposition was one of the chief accomplishments of the period of expansion in evolutionary thought from the 1920s to the 1950s, which Huxley (1942; 1887–1975) termed the “modern synthesis” (Young, 2007; Bowler, 2009).

In the initial phase of the synthesis, mathematical population geneticists, prominently Fisher (1930; 1890–1962), Wright (1931; 1889–1988), and Haldane (1932; 1892–1964), showed that Darwinian natural selection was compatible with Mendelian inheritance, and worked out the dynamics of genes in Mendelian populations under the influence of mutation, selection, and population structure.

In the second phase, the synthesis of Darwinism and Mendelism was expanded to include diverse subdisciplines of biology. Key to this development was the Russian–American empirical population geneticist Theodosius Dobzhansky (1900–1975). His work, growing out of the Russian school associated with Sergei Chetverikov (1880–1959), which stressed the study of natural populations, made the developments in both theoretical and empirical genetics available to a wider audience. Dobzhansky’s (1937) seminal *Genetics and the Origin of Species* was followed by important synthetic works by the zoologists Mayr (1942; 1904–2004) and Rensch (1947; 1900–1990), the morphologist Schmalhausen (1949; 1884–1963), and the botanist Stebbins (1950; 1906–2000). The integration of paleontology with population genetics by Simpson (1944, 1953; 1902–1984) demonstrated that the synthetic theory of evolution was fully consistent with the fossil record. Alternative theories of the mechanisms of evolutionary change that had been formulated since Darwin but prior to the evolutionary synthesis, such as neo-Lamarckism and the view that biological systems were creative and purposeful, were demonstrated to be inconsistent with the fossil record.

The major achievement of the evolutionary synthesis was thus to fully integrate genetics and Darwinian evolution, and to demonstrate that evolutionary patterns and processes seen in natural populations and the fossil record were consistent with Darwinian natural selection, the hereditary mechanisms discovered by laboratory geneticists, and the theories of mathematical population genetics (Futuyma, 1998, 2009).

Postsynthesis Developments

As noted in the section What Evolution is, there are two central questions in evolutionary biology: the first asks, what are the mechanisms of evolution; that is, what are the causes of the history of life? The second asks, what is the history of life, as defined by the history of species, their origins, and extinctions, and what are the steps through which organismal features evolved? Although the major principles of evolutionary biology and major causes have been established, new questions are continually posed and many long-standing questions remain to be fully answered. In the postsynthesis period, these questions have been addressed in a broadening array of disciplines that have contributed to understanding evolutionary history and mechanisms, including such fields as evolutionary ecology, behavioral evolution, evolutionary paleontology, evolutionary developmental biology, evolutionary

physiology and morphology, evolutionary systematic biology, evolutionary genetics, molecular evolution, and human evolution. Research in all of these fields, and the interdisciplinary overlaps between them, have accelerated in the past 30 years. Two areas of explosive research deserve special mention.

First, the field of molecular evolution, from being scarcely existent in 1950, has become a burgeoning field comprising a large part of the research program of evolutionary biology (Higgs and Attwood, 2005; Edwards, 2009). It was realized early on that, once available, molecular sequence data, of either amino acids or DNA, would be “documents of evolutionary history” (Zuckerandl and Pauling, 1965) and that branching sequences, ancestral states, and rates of evolution could be estimated from such data. This realization has proven abundantly true, and molecular data now form the basis of the phylogenetic estimates for large swaths of the tree of life (Felsenstein, 2004; Hall, 2011; Hillis, 2010).

Molecular data have contributed to the understanding of not only evolutionary history but also evolutionary mechanisms. In the 1960s, protein electrophoresis revealed high levels of genetic variation in natural populations, which answered old questions about the amounts of natural genetic variation and posed new ones about the maintenance of variation (Lewontin, 1974). The advent of DNA sequencing has revolutionized evolutionary molecular genetics (Kreitman, 1983), and such data now allow hypotheses about the relative importance of drift and selection on particular loci and regions to be effectively tested (Charlesworth and Charlesworth, 2010). As well, the sequencing of whole genomes of an ever-expanding variety of organisms has led to the emergence of comparative genomics, in which entire genomic structures can be compared, and their evolutionary histories and the forces shaping them studied (Lynch, 2007; Edwards, 2009).

The second is the field of evolutionary developmental biology, or “evo devo” as it is known, another field that scarcely existed in 1950. It too has become a vibrant research program, focused on the study of the developmental pathways by which organismal features are produced, the genetic basis of alterations in these pathways that are evolutionarily incorporated within lineages, and the biases or constraints that may be imposed on phenotypic evolution by these alterations. Most of evolution is the modification of preexisting structures, and these structures arise in the organism via a process of epigenetic (in the original sense: Haig, 2004) development. Thus, most of evolution is the modification of preexisting developmental programs. To understand phenotypic evolution, one must understand the variations that alterations of the developmental program can give rise to, their natures, and frequency, and these studies are the domain of evo devo (Carroll, 2005; Carroll *et al.*, 2005; True, 2009; Wray, 2010; Stern, 2011).

One of the most exciting developments in this field has been the discovery of a number of developmental regulatory genes, such as Hox genes, that regulate the spatial expression of genes in developing animal embryos, and which are conserved among taxa as disparate as arthropods and vertebrates. The two major groups of bilaterian animals – the protosomes (Ecdysozoa and Lophotrochozoa) and the deuterostomes (Chordata and Echinodermata) – share a common genetic regulatory repertoire and are characterized by an extensive

cluster of Hox genes that bind to DNA and control interacting networks of developmental regulators and key structural genes (Knoll and Carroll, 1999) (Figure 2). This repertoire of genes, which was present in the common ancestor of the Bilateria, has been referred to as a “genetic toolkit” for the development and evolution of basic animal morphologies, and understanding their action and evolution will aid in understanding such features as germ layers, coelom formation, and spatial organization (Carroll *et al.*, 2005).

Darwin's Five Theories

Although Darwin often used expressions such as “my theory,” he actually proposed a number of distinct, though related, theories. Some, such as his theory of inheritance, termed “pangenesis,” were wrong and are of historical interest only. But a cluster of other theories has been borne out by subsequent developments in evolutionary biology, and it is useful to consider these ideas here. Mayr (1991, 2001) has identified a set of these ideas as “Darwin's five theories,” and his usage has been followed and adapted by later authors (Futuyma, 1998, 2009; Coyne, 2009), and the following account is adapted from this approach.

The first is evolution as such, the simple idea that later organisms are the modified descendants of earlier organisms. This idea had also been advocated by Lamarck. Darwin convinced essentially all of his scientific contemporaries of the truth of this proposition. The evidence for this may be found in any evolution textbook (e.g., Freeman and Herron, 2007; Hall and Hallgrímsson, 2008; Futuyma, 2009), and in more popular expositions by Coyne (2009) and Dawkins (2009).

The second is common ancestry, which had been rejected by nontransformists such as Cuvier, who held that the four “embranchements” of animal life (Vertebrata, Radiata, Articulata, and Mollusc) were so essentially different that they could not be connected by any possible transformation (Young, 2007). Common ancestry may seem to follow from evolution as such, but it does not: Lamarck, it will be recalled, proposed continual spontaneous generation, with each origination progressing up the chain of being, and thus not being genealogically related to earlier or later originations. Darwin (1859, p. 490) proposed that life had been “breathed into a few forms or into one,” and thus most or all organic beings would be connected by a single tree of life. This contention has been abundantly borne out by phylogenetic studies within eukaryotes, but the eukaryotes appear to be chimeric in their origin, incorporating by lateral or horizontal gene transfer both Archaeobacterial and/or Eubacterial genes in their nuclear and organellar genomes. A phylogenetic tree based on small subunit RNA places the eukaryotes as sister to the Archaeobacteria (Knoll, 2003), but large-scale genomic analyses are in disagreement about the nature, extent, and phylogenetic significance of the shared genomic components. Although some whole genome incorporation via endosymbiosis (e.g., mitochondria) is well established, the possibility of extensive lateral transfer of genes among prokaryotes and early eukaryotes has led Lynch (2007) to ask if life is a tree, ring, or web; resolution of the relationship among the domains of life remains a major task for phylogenetics (Gribaldo *et al.*, 2010) (Figure 3).

Figure 2 Animal diversity across the Proterozoic–Cambrian transition. By 510 Ma, all higher-level taxa of animals indicated had diverged. Bilaterians are characterized by triploblasty, a rostral–caudal axis, a dorsoventral polarity, and an extensive cluster of Hox genes. Reprinted from Knoll AH and Carroll SB (1999) Early animal evolution: emerging views from comparative biology and geology. *Science* 284: 2129–2137.

The third is gradualism, the idea that evolutionary divergence accrues incrementally by small steps. For Darwin, large changes that could produce or maintain adaptation would be akin to miracles. Although there is still debate (Stern, 2011), the modern consensus agrees with Darwin in rejecting saltational evolution, for a variety of reasons. Prominent among these are that mutations of large effect are usually accompanied by deleterious pleiotropic effects, which would make such mutations selected against, and the many fossil sequences documenting the origin of higher taxa via numerous intermediate steps. For example, that tetrapods evolved from lobe-finned fishes has long been known, and the discovery of fossils near the transition such as *Panderichthys* and *Tiktaalik* is filling in the structural differences between fish and amphibian, so that one can see exactly how, among other changes, legs gradually arose from fins. From the evidence of at least vertebrate paleontology (Prothero, 2007; Shubin, 2008; Laurin, 2010), one can say that most of evolution is the gradual, adaptive modification of preexisting structures or, better, their underlying developmental programs.

The fourth is that evolutionary change is populational or variational. Lewontin (1983) has argued that this is the most distinctive aspect of Darwin's thought. Rather than consisting of the transformation of individuals, Darwin proposed that individuals in a population have varying heritable properties and that evolution consists of changes in proportions of these

heritable properties within the population. Some properties persist or increase in frequency, whereas others disappear, so that the hereditary constitution of the population as a whole changes.

Finally, there is natural selection, which Darwin considered the chief, though not the only, means of changing the frequency of the hereditary properties in populations and the evolutionary force most able to produce that adaptation to the conditions of existence, the absence of a compelling explanation for which had been a chief stumbling block for evolutionary hypotheses. Darwin proposed that, if the hereditary properties of individuals conferred on those bearing them varying propensities to succeed in the struggle for existence and reproduction, then those properties that conferred higher survival and/or reproduction (i.e., higher fitness) would increase in frequency in subsequent generations.

Evolutionary Mechanisms

Variation

Because the theory of evolution is variational, asking how much variation there is in natural populations is one of the key questions of evolutionary biology (Lewontin, 1974; Charlesworth and Charlesworth, 2010). And the answer is that

Figure 3 (a) The three “domains” of living organisms. The origin of the Eukaryotes (all multicellular organisms) has involved the combination of genomes from the Archaeobacteria (methane-producing bacteria and bacteria living in extreme environments) and the Eubacteria (all remaining single-celled organisms). Lateral transfer (b) of genetic information among lineages complicates representation of the phylogeny, since it is not a pure branching, but also a reticulating, process. Reproduced from Martin W (1999) Mosaic bacterial chromosomes: A challenge en route to a tree of genomes. *BioEssays* 21: 99–104, with permission from Wiley-Liss Inc., a subsidiary of Wiley & Sons Inc.

variation in natural populations is ubiquitous. Since the nineteenth century, it has been clear that there is abundant variation within species in morphological characteristics such as size, shape, color, pattern, number, and so on, and this observation has been extended to behavioral and physiological traits. An important step in the synthesis was the demonstration of the genetic, and specifically Mendelian, basis of much of this variation (Young, 2007). As well, the results of animal and plant breeders had demonstrated an abundance of heritable variation within species.

In the twentieth century, the ability to directly examine proteins and then DNA sequences has confirmed the ubiquity of variation and extended it to the molecular genetic level. A species' genetic composition does not consist of a wild-type genotype with rare mutations, but rather a very large number of genotypes, with polymorphism at the protein level on the order of 30% of loci and 10% of individuals heterozygous. In a sexual species, virtually every individual is genetically unique (Freeman and Herron, 2007; Futuyma, 2009).

The Causes of Evolution

Mutation

A population may be characterized by the frequency within it of its various genotypes or genes. Since evolutionary change is variational – change in the distribution of heritable properties in populations – the causes of evolution are those forces that can change the frequencies of heritable properties in populations. One way in which these frequencies can change is to have new genotypes produced by changes in the genetic material during reproduction. Such changes may be broadly termed “mutations” and may result from errors in the genetic copying process or from environmental insults such as radiation or mutagenic substances. Recombination during sexual reproduction will also produce new genotypes. Mutations may be genic, affecting small sequences of DNA by nucleotide substitution, insertion, or deletion, or they may be chromosomal, affecting larger segments or whole chromosomes by rearrangement of segments and/or changes in chromosome number.

Mutation is of fundamental importance as the ultimate source of new genetic variation. Mutations are random, meaning that the probability of a mutation occurring is unrelated to whether or not it fits the organism to its conditions of existence (i.e., whether or not it is beneficial or deleterious). Mutations thus do not drive adaptation. The randomness of mutations does not mean that all mutations are equiprobable or that any conceivable phenotypic effect is achievable by mutation. A conceivable structure, without a preexisting developmental or structural basis, is difficult to get by mutation. Only phenotypes that can result from alteration of an existing developmental process are mutationally accessible. A Pegasus-like winged horse would be mutationally difficult, because horses (as do tetrapods generally) have four limbs, not six. An existing limb, however, can easily be modified: made longer or shorter, thicker or thinner, bony elements reduced or (more rarely) increased.

Despite being an evolutionary force of fundamental importance, mutation is nonetheless a weak evolutionary force, because observed rates of mutation are inadequate to cause rapid evolutionary change on their own, and even less so if selection acts counter to mutation (Futuyma, 2009).

Migration

The distribution of heritable material in a population may change if individuals enter the population, thus bringing potentially different genes or genotypes into the population. This movement of individuals is called migration, or gene flow. If the genetic constitution of incoming migrants differs from that of the recipient population, then the genetic composition of the population will change, and the effects can be substantial. Human populations have been especially well documented genetically, and the major effects of migration on gene frequencies have been documented and mapped (Cavalli-Sforza *et al.*, 1994); since the advent of rapid intercontinental travel around 1500, even more changes in human genetic population composition have occurred, and parts of the Americas especially are now inhabited by populations strongly shaped by migration.

The chief effect of migration is to retard divergence among populations between which migration is occurring: it leads to the genetic homogenization of populations. It thus tends to oppose the forces promoting differentiation, which is what drift and selection tend to do. Indeed, Futuyma (2010) has proposed that the main constraint on adaptive divergence is that such divergence, in either time or space, is ephemeral in the face of migration from nondivergent or alternatively divergent populations, which erases the evolved differences.

A second way in which different genes or genotypes can enter a population is not from migrants of the same species, but from other species, sometimes quite distantly related, through lateral or horizontal gene transfer. The importance of hybridization in, especially, plant evolution has long been known (Stebbins, 1950), and more recent work has shown the fundamental importance of lateral transfer in prokaryotes and the origin of eukaryotes (Knoll, 2003; Lynch, 2007), but examples are now known of adaptive evolution by lateral transfer involving higher eukaryotes, including fungus-to-animal transfer (Moran and Jarvik, 2010; Zhaxbayeva and Doolittle, 2011).

Genetic Drift

Even if there is no mutation or migration, the genetic composition of the offspring will differ from that of the parents, because reproduction is a probabilistic sampling process. Suppose two genetic variants are present in a population in equal frequency (50% each). It would then be expected that the same proportions be present in the next generation. Suppose the total population is 40. The expectation would be 20:20, but it wouldn't be surprising if it is 19:21, or even 23:17. It is like flipping a fair coin: one would expect 50% heads only in a very large number of tosses; in a few tosses, one might get mostly heads or mostly tails. The same is true of populations: the larger the population, the nearer to the expected proportions; the smaller the population, the more frequent and greater the departures from expectation. The direction of change in frequency of the variant – up or down – is random, and once changed, there is no tendency to move back toward the initial frequency. Thus, the frequency of the genetic variants will wander randomly, and this wandering is called genetic drift.

The strength of drift is inversely proportional to population size: it is more important in smaller populations. Drift has two main effects on the genetic composition of populations. First, it decreases variability within populations

(because some variants will drift to extinction), and second, it will cause divergence among populations (because different variants will drift to high or low frequency independently in the various populations) (Charlesworth and Charlesworth, 2010). For variants that are neutral with respect to selection (i.e., that do not differ consistently in their effects on the survival or reproduction of their bearers), drift will be an important force, and, if populations are small enough, even nonneutral variants can be strongly affected by drift (Graur and Li, 2000).

Selection

Drift is random differences in survival and reproduction. Sometimes, though, there will be good, deterministic reasons why variants differ in survival and reproduction, such that there is a predictable propensity for some variants to be represented at higher frequency in subsequent generations due to their greater survival and/or reproduction. This consistent (i.e., nonrandom) differential survival and/or reproduction is natural selection. It is important to note that this is not how selection acts, or the means of selection, or the result of selection: consistent differential survival and/or reproduction is selection.

Natural selection is the only evolutionary force that can produce adaptation – the fit between organisms and their conditions of existence. In modern evolutionary theory, one can define an adaptation as a derived feature of an organism that increases the survival and/or reproduction (i.e., fitness) of the organism by virtue of the possession of that feature. This definition distinguishes features that are adaptations from features that do not increase fitness (effects, such as the red color of blood due to iron in hemoglobin, as opposed to the adaptive nature of the oxygen-binding capabilities of hemoglobin) and features that may be useful, but which are already present (e.g., the skull sutures of mammals that are not adaptations for passage through the birth canal, but rather an inheritance from reptilian ancestors; Williams, 1966; Futuyma, 2009).

Natural selection is well documented as a cause of evolutionary change in populations (Endler, 1986; Freeman and Herron, 2007; Grant and Grant, 2008; Futuyma, 2009). There is widespread agreement that natural selection can produce adaptations of organisms through differential survival and/or reproduction of genes or individuals. Whether there can be selection among groups, populations, or species, so as to produce adaptations at these levels of organization, is much debated (Gould, 2002; Coyne and Orr, 2004; Futuyma, 2009).

Speciation

Mutation supplies the raw material of variation. Migration, drift, and selection are the forces that effect the fate of that variation within lineages; with respect to nonneutral variants, it can be said mutation proposes, selection disposes. The four evolutionary forces cause evolutionary changes, and these changes within a single ancestor–descendant lineage are called anagenesis. But if evolution consisted only of anagenesis, there would be only one kind of organism – changing over time, but just one lineage. To produce the great contemporaneous diversity of organic beings that inhabit Earth, there must be a multiplication

of lineages. The generation of new lineages is called cladogenesis or speciation (Coyne and Orr, 2004; Price, 2008).

For the study of evolutionary mechanisms, including speciation, the most fruitful concept of species, at least for sexual forms, is the biological species concept (Coyne and Orr, 2004). Under this concept, species are groups of actually or potentially interbreeding populations in nature, which are isolated from other such groups by reproductive isolating barriers. Reproductive isolating barriers include phenomena such as courtship behavior, pollinator specificity, and hybrid sterility, all of which act as barriers to the exchange of genes between species. Under the biological species concept, the question of how species originate is the question of how reproductive isolating barriers arise.

One way to achieve this is to divide a population into two or more spatially separated populations, so that migration – a homogenizing force – is no longer possible between the spatially separated descendant populations. Each population initiates an independent lineage, within which mutation, migration, drift, and selection will convert individual variation into variation in time and, because the independent lineages coexist in time, into variation in space. If this independent anagenesis leads to the populations changing so much that they are reproductively isolated (e.g., their mating calls change to the point where they no longer recognize one another as potential mates), then the descendant populations will be able to coexist in the same place without losing their identity through interbreeding: they will have become separate species.

This scenario of geographic isolation is one mode of speciation, called allopatric speciation. It is the conversion of an initially extrinsic isolation (geographic separation) into intrinsic reproductive isolating barriers. There are other possible scenarios, which involve such possibilities as selection acting to reinforce reproductive isolating barriers, or little or no initial geographic separation (parapatric and sympatric speciation). Allopatric speciation is widely accepted (Mayr, 1942), whereas there remains considerable debate about at least some aspects of other modes of speciation (Coyne and Orr, 2004; Price, 2008).

As speciation is repeated over time, there is a potentially exponential increase in the number of species, and the ramifying, branching history of life over time is the phylogenetic tree. Different branches of the tree will speciate and go extinct at different rates. Some branches will undergo adaptive radiations, in which the varied species will come to occupy a diversity of stations in the economy of nature on scales from the archipelagic (Grant and Grant, 2008; Losos, 2009) to the continental (Lull, 1917). The lineages of the various branches will interact with one another and with their environments, and will disperse over, and move about with, the wandering continents and oceans. This constitutes biotic evolution, the evolutionary history of the set of all organic beings, and this is the history of biodiversity on Earth.

Glossary

Correlation Determining the relative age of strata.

Extant Having some living representatives (i.e., not extinct) at a particular time.

Ma An abbreviation of the Latin “mega-annum” used by paleontologists to indicate dates millions of years before present.

Molecular phylogenetics The study of the history of evolutionary relationships according to similarities and differences among (usually extant) organisms in molecular characters (such as DNA).

Parametric statistics Statistical methods that assume data have certain characteristics, such as a particular kind of distribution (Poisson, normal, binomial, etc.).

Stage Normally the lowest-ranking unit in the hierarchy of terms for stratigraphic intervals that can be recognized on a global scale.

Stratigraphic interval All (and only those) rocks formed during a specific interval of geologic time.

Stratigraphic range The strata through which a taxon is known to have been extant.

Stratum (plural:strata) A unit of sedimentary rock distinguishable from other units on the basis of properties and/or relative position.

Taxon (plural:taxa) A group of organisms that share a name.

Obtaining reliable estimates of biological diversity in the fossil record is critical to addressing key questions about changes in biological diversity over long timescales and the causes and consequences of those patterns. On what scales is the history of life characterized by periods of stasis punctuated by relatively brief periods of rapid evolutionary change? On what scales is it a more gradual, continuous process? What are the causes of these changes? How often are major changes in biodiversity associated with major changes in the physical environment, such as extraterrestrial impacts? How have human impacts changed biodiversity? Unfortunately, the fossil record provides an incomplete picture of the history of biological diversity. This article reviews some important features of the fossil record that could cause the apparent history of biodiversity to differ quite markedly from its true history. It then introduces several methods that have been applied in an attempt to account for these features, it discusses advantages and disadvantages associated with each of them, and it reviews how their application in specific cases has altered earlier views about changes in diversity through time. Throughout this article, the terms “diversity,” “biodiversity,” and “biological diversity” will refer to taxonomic richness: the number of taxa present at a particular time or place. Although alternative metrics of diversity have been proposed, most paleobiologists have focused on taxonomic richness, at least when addressing regional or global patterns in biodiversity.

The Nature of the Fossil Record

The fossil record is an incomplete sample of the original living community, and, like most biological samples, some taxa are under-represented (e.g., soft-bodied worms from desert

environments) relative to others (e.g., clams from soft-sediment marine habitats). Fossil assemblages are accumulations of organisms that share a common grave, but that may not have been alive at the same time or place. The ages of individual fossils are rarely determined, and, typically, fossil assemblages are assigned to a time interval that can range from thousands to millions of years. Any paleontological study larger than the local scale must place fossils from different locations onto a common time scale, which limits temporal resolution because the ages estimated for fossils include some degree of uncertainty, and coarser temporal resolution ensures that samples are put in the correct temporal sequence.

The Fossil Record is Incomplete

The fossil record is incomplete: Only a small fraction of individuals are fossilized; of those, very few are collected and identified. As a result, the biological diversity recorded in the fossil record is less than total diversity over the region and time interval from which it is a sample, and the observed stratigraphic ranges of taxa are shorter than their true ranges. This is because the first appearance of a taxon in the fossil record occurs sometime after it actually originated, unless it's very first representative was fossilized and subsequently sampled (a highly unlikely prospect). Similarly, the last appearance of a taxon occurs sometime before it actually went extinct. Biased estimates of stratigraphic ranges are important for the study of trends in biodiversity because such ranges have traditionally been used to estimate biodiversity. Thus, rather than estimating diversity as the number of taxa that actually occur in samples from a particular stratigraphic interval, diversity has been estimated as the number of taxa whose stratigraphic ranges encompass the interval. The use of

stratigraphic ranges to estimate diversity leads to underestimates of biodiversity, because true times of origination precede the first appearance of a taxon in the fossil record, and true times of extinction come after a taxon's last appearance in the fossil record.

The Quality of Preservation Varies

If incomplete sampling were the only problem with the fossil record, it would still be possible to accept relative trends through time at face value – that is, an increase in diversity in the fossil record would indicate a real increase in biological diversity, even if the true number of taxa could not be determined. Unfortunately, however, the degree to which the fossil record is incomplete varies in both space and time. Despite notable exceptions, such as the Burgess Shale or Solnhofen Limestone, most fossil assemblages record only hard parts. Thus, organisms with hard parts are much more likely to be preserved in the fossil record than those without them. Clams, for instance, have a better fossil record than nematodes. One consequence of this is obvious: the difference between apparent and true diversity tends to be greater for the latter group than for the former. However, estimates of diversity trends through time can be affected as well, if the proportion of taxa with body parts that are readily fossilized changes. Indeed, some have argued that the “Cambrian explosion” represents, not a diversification of multicellular life, but a rapid and extensive proliferation of hard parts. This hypothesis is supported by molecular phylogenetic studies predicting that the major animal phyla diverged long before the early Cambrian (~542 Ma). The timing of this divergence remains controversial; nevertheless, the very fact that it has received considerable attention illustrates just how profoundly sampling effects may influence the fossil record of major events in the history of life.

Differences in abundances among taxa can also affect their preservation in the fossil record. It is individuals (or parts of individuals) that are fossilized; thus, more abundant taxa are, on average, likely to have more complete fossil records than will rare taxa. Further, fossil diversity is likely to be higher for intervals during which abundances were higher, on average, than during other intervals. This, too, has important consequences for inferences about diversity trends. For instance, several major episodes of diversification, as recorded in the fossil record, coincide with geophysical changes that probably increased rates of nutrient supply to the biosphere. Some workers have argued that these geophysical changes were important causes of the coincident biological diversification. However, if increases in rates of nutrient supply also allowed taxa to sustain higher abundances, then increased probabilities of preservation during those intervals could be contributing to the increased diversity. Thus, inferences about the causes of trends in biodiversity, in addition to inferences about the trends themselves, can be influenced by sampling effects.

Differences in abundance or geographic range can also affect estimates of stratigraphic ranges. One of these effects is illustrated by the previous example: when comparing two intervals, more first appearances will be found in the interval

with greater average abundance or geographic range size, even if there were, in fact, an equal number of originations during the two intervals. Assessing the severity of this effect is complicated by the fact that there are sound biological reasons for increases in abundance to facilitate originations of new taxa: to the evolutionary biologist, a correlation between abundance and rate of speciation may be precisely what is expected!

Yet another characteristic of organisms that can affect inferences about biodiversity trends is habitat. In particular, individuals in some habitats are more likely to become fossils than individuals in others. For instance, marine soft-bottom habitats are likely to provide more complete records of their inhabitants than will rocky shores. In the former case, individuals will much more readily be buried shortly after (or even before) they die. In the latter, wave action may render the remains of individuals unidentifiable before currents carry them to a location where they might be buried and preserved. Indeed, the fossil record of rocky shore communities is among the poorest in the marine realm. Again, the difficulties associated with these effects has led to disagreements about key events in the history of life. For instance, fossils record an explosive diversification of mammals in the early Tertiary, following the mass extinction that ended the Cretaceous period (best known for catastrophic extinctions among dinosaurs; 65.5 Ma). Most workers believe that this reflects the true pattern, at least qualitatively. However, others, using molecular phylogenetics, have argued that much of this diversification occurred in the Cretaceous, prior to this mass extinction. One explanation for this discrepancy has been that these early Cretaceous mammals occupied habitats with lower potential for preservation (such as forest interiors) than for their Tertiary descendants, who expanded into new habitats to occupy niches vacated by the extinction of dinosaurs. Whether this discrepancy between molecular and fossil data is primarily due to a poor fossil record for Cretaceous mammals or to biases and uncertainties in the molecular methods remains controversial.

As the discussion of the effects of habitat preference suggests, the probability of an individual being preserved in the fossil record depends, in part, on the sediments themselves. The existence and availability of fossiliferous rock, too, can have profound consequences on inferences about diversity patterns. For instance, in a classic paper, [Raup \(1976\)](#) noted a systematic increase in the volume of sedimentary rock through time. The implication was that the probability of individuals being preserved in the fossil record becomes progressively greater through time. Indeed, he presented a graph of sedimentary rock volume through time that looked strikingly similar to a graph showing biological diversity in the fossil record through time. After removing the effect of rock volume on diversity, he found no evidence for a long-term increase in species diversity through time. This line of research has been revived by Peters and others, particularly with regard to the effects of changes in rock volume on origination and extinction rates ([Peters, 2006](#)). Recent attempts to account for such effects have substantially reduced the magnitude of the diversity increase over time and changed our understanding of the timing of extinction events, relative to data that ignores such systematic changes in the fossil record.

The extent and quality of the fossil record varies over smaller timescales as well. Geophysical transitions can dramatically affect the probability that individuals will be preserved as fossils. When these transitions are global in scope, or occur in regions that receive disproportionately large amounts of attention from paleontologists, then apparent changes in diversity can result. Just such a possibility has complicated analysis of what was probably the most extensive mass extinction in the history of life, an event that marks the end of the Permian and the beginning of the Triassic. This event coincided with a major loss of marine benthic habitat (due to decreasing sea level). While it is certainly reasonable to suspect that biodiversity would decrease as available habitat decreases, it also reduces the probability of sampling taxa that remain, a phenomenon known as the Signor–Lipps effect. This and other sampling effects associated with characterizing this extinction event and its aftermath are extensively reviewed by Erwin (2006).

The Extent of Sampling Varies

Decisions paleontologists make can also introduce, or exaggerate, differences in the quality of the fossil record. For instance, North America and Europe have been more extensively sampled than many other regions of the world. This reflects, in part, the fact that many paleontologists live on these two continents. The logistical problems associated with fieldwork are generally less severe, and the cost of travel lower, when fieldwork is conducted near a home institution. In addition, fieldwork tends to be easier in regions with a well-developed infrastructure. As a result, more of the preserved biodiversity is actually sampled and recorded, and thus the apparent diversity of well-sampled regions is higher than that of poorly sampled regions. In the fossil record this is especially problematic as certain areas preferentially record specific time intervals and environments. For example, the marine fossil record of North America mainly represents tropical marine environments during the Paleozoic (251–542 Ma) but temperate marine environments in the Cenozoic (0–65 Ma).

Similarly, the questions that one can ask of paleontological data, and the degree of confidence that can be assigned to answers, depends in large measure on the quality and quantity of data that can be collected. For instance, more workers focus on the most recent era of time, the Cenozoic, than on the previous era, the Mesozoic (65–251 Ma), despite the fact that the latter era was longer in duration. This tends to exaggerate the effects of more abundant Cenozoic fossils. Likewise, more paleontologists study the Mesozoic than the earlier Paleozoic, again potentially amplifying the effects of greater availability of Mesozoic fossiliferous rock.

Correlation and Dating

Yet another factor affecting estimates of diversity patterns is correlation and dating. When fossils are collected, their age is generally inferred according to the particular strata in which they were found. Because direct age estimates are not available for most locations, age assignments are generally based on the presence of particular indicator taxa. That is, strata containing

particular indicator taxa are assigned to a particular time interval (not a specific point in time) based on the presence of the indicator taxa in other dated strata. Since new taxa originate at a point in space as well as time, there is some uncertainty due to the rate at which the indicator taxa increase their geographical ranges. In practice, paleontologists attempt to minimize this problem by using multiple indicator taxa. They also select indicator taxa that are likely to have high probabilities of preservation in the fossil record and whose spread is likely to have been rapid, such as planktonic foraminifera.

Because data are assigned to intervals rather than points in time, the number of taxa found in a particular interval may be greater than the number of those taxa that were actually extant at any particular point in time during that interval (assuming that extinctions or originations occurred during the interval). The longer the interval lasts, and the higher the rates of origination and extinction, the more apparent diversity is inflated. Because it is the proportional difference in length that is critical here, this problem becomes more severe as intervals are more finely divided. The shorter the interval, the greater the proportional uncertainty associated with the estimated ages of the intervals' boundaries. For instance, overestimating the duration of a 10 million year interval by 1 My inflates the estimated duration of that interval by 10%. However, an overestimate of the same magnitude on the duration of a 3-My interval represents a 33% inflation. Fortunately improved dating techniques and concerted efforts by geologists and paleontologists have led to ongoing improvements in the geologic time scale (Gradstein *et al.*, 2005).

If one is interested in estimating global diversity or macroevolutionary rates, then the temporal resolution of investigation is limited by the ability to correlate stratigraphic intervals. At the global scale temporal resolution is typically limited to ~90 internationally recognized stages which average ~6 Myr long, but can vary in length by more than a factor of 10. If the origination and extinction of taxa occurred at roughly constant rates, then variation in the length of international stages could be responsible for a 10-fold difference in apparent diversity! The Paleobiology Database (<http://paleodb.org/>) has attempted to address this problem by grouping shorter stages and creating 48 time intervals, each approximately 11 My long. These intervals are more uniform than stages, but they can still vary by a factor of three due to difficulties subdividing a few time intervals.

Statistical Estimation of Diversity Trends

Until recently, nearly all large-scale studies of paleontological diversity took the first and last appearances of taxa in the fossil record as a true record of its times of origination and extinction. In taxa with relatively poor sampling, but widely-accepted phylogenetic trees, such as dinosaurs, first occurrence times have been extended based on the estimated times of origin obtained from the phylogenetic trees. However, for the reasons described in the previous section, this practice is now widely recognized as inadequate. More recent compilations of data, initially by individual researchers but increasingly by large teams, such as the Paleobiology Database, are beginning

to make large-scale analyses possible, by recording the spatial and temporal pattern of fossil occurrences. That is, rather than simply a time of first and last appearance, there is a record of the occurrences of a particular taxon in the fossil record over time and space. Such occurrence patterns contain valuable information about the completeness of the fossil record. For instance, consider the taxa that are found both before and after, but not within, a particular time interval. While not sampled these taxa must have been present during that interval. The proportion of taxa that do not have fossil occurrences in that interval but must have occurred during the interval, provides information about the completeness of the fossil record during that interval. The accessibility of large datasets has led to substantial growth in the use of statistical methods that seek to use occurrences in various ways to obtain better estimates of diversity, or at least of changes in diversity.

Sampling Standardization

One way to control for sampling effects in making inferences about diversity trajectories is to compare taxonomic richness among locations or strata with samples that have been standardized to be equivalent in extent, according to some reasonable measure. The simplest standardization technique, called rarefaction, works as follows: A sample is collected from each of a set of habitats (for instance, a certain volume of sediment is obtained) using an identical sampling scheme. All of the individuals in each sample are identified, and their taxonomic identity is recorded. The next steps can be visualized by imagining placing all of the records for a particular sample in a bowl, stirring them, and then randomly selecting records from that bowl until none are left. Each time a record is picked, the taxonomic identity of that record is noted. From this sequence of random draws, one constructs a graph with the number of records on the horizontal axis and the number of distinct taxa on the vertical axis. What is plotted on that graph are the results of that sequence of record selection. This curve must intersect the points (0, 0) and (1, 1). That is, before the experiment begins, 0 records have been picked from the bowl, so 0 distinct taxa have been selected. When one record is chosen, exactly one distinct taxon has been found. When two records have been chosen, either one or two distinct taxa have been found. (If the second record has the same taxonomic identity as the first, the next point is (2, 1); if it has a different identity, the next point is (2, 2)). Once all of the points have been plotted, a curve is fit to them: this is the rarefaction curve. This process is repeated for each sample collected, so that each sample has a rarefaction curve associated with it. Biodiversity in the different samples is then compared by examining the number of distinct taxa encountered for a given number of records selected. That number must be equal to or less than the number of records in the sample with the fewest records. This comparison is illustrated in Figure 1.

Figure 1 also illustrates something else: Rarefaction curves sometimes cross. This means that the rank order of diversities of a set of samples can change, depending on sample size. These relative changes depend upon the relative frequencies of occurrence of different taxa. For instance, if taxa have similar sampling probabilities (e.g., because they have similar

Figure 1 Hypothetical rarefaction curves for three samples representing three different habitats, designated A (solid line), B (dashed line), and C (dotted line). Note that habitat A, whose sample contains the most taxa in its entirety (note that its rarefaction curve ends at a higher diversity than the others), is not the most diverse habitat when its diversity is compared with the others for a particular sample size (X_1 on the horizontal axis). Also note that the rarefaction curves for samples B and C cross. Thus, habitat B is more diverse when there are X_1 records in the sample, but habitat C is more diverse when there are X_2 records.

abundances), then the rarefaction curve will tend to quickly accumulate all available taxa. However, if occurrences are unevenly distributed among taxa, then initially diversity will increase very slowly, as the dominant species are sampled, but very rare species will still be occurring for the first time even as the standardized sample approaches the size of the original sample. One might therefore ask what rarefied diversity means, and, further, what it means to say that one site has a greater rarefied diversity than another. Hurlbert (1971) proposed that rarefied diversity measures the number of distinct taxa encountered, on average, by an individual organism in a particular habitat over the course of a particular number of encounters with other individuals (provided that individuals are not encountered multiple times). The fact that one habitat has a greater rarefied diversity than another for a given number of occurrences of individuals does not mean that that habitat actually has a greater taxonomic richness (i.e., contains more taxa) than another.

Although rarefaction can be applied to the fossil record in the manner just described, it is often applied somewhat differently. When comparing diversities over very large scales (e.g., global diversity during two stratigraphic intervals), a sample enumerating all of the individuals in those intervals will not be available. Rather, data will consist of a number of distinct samples for each of the intervals being compared. Further, while a list of the taxa found in each sample may be available, information on the abundances of those taxa may not. Such data have been rarefied in two different ways. In one approach (hereafter called rarefaction by occurrence), a rarefaction curve is constructed by randomly selecting occurrences of taxa from the set of available samples. The rarefaction curve is then a plot of the number of distinct taxa sampled against the number of occurrences of taxa drawn

Figure 2 A graphical illustration of rarefaction by occurrence. Occurrences of a taxa within samples are treated independently, and these occurrences are drawn individually at random from the set of occurrences in all samples. This can be visualized as adding each occurrence individually (regardless of the sample from which it comes) into a pool (arrows into the black box), then randomly choosing these occurrences from that pool (arrows out of the black box). In this figure, the rarefied diversity after five records have been drawn is four distinct species.

from the available samples. This is illustrated in **Figure 2**. Diversities are compared by constructing these rarefaction curves for each interval. An alternative approach (hereafter called rarefaction by list) involves randomly selecting the entire list of taxa present in a given sample as a unit, rather than selecting occurrences of taxa within those samples. In this case, the rarefaction curve for a particular interval consists of the number of distinct taxa detected plotted as a function of the number of samples drawn. Note that in this instance, the curve is not constrained to pass through the point (1, 1), since several taxa may appear in a single sample. However, it still must pass through the point (0, 0). This method is illustrated in **Figure 3**. As with rarefaction by occurrence, rarefaction curves can cross in this case also, depending on the pattern of alpha and beta diversity (i.e., whether diversity is due mainly to there being many taxa present in individual locations, or due to different locations having very different suites of taxa).

In a quest to exploit the information contained at multiple levels (e.g., published references, lists within references, occurrences within lists), paleobiologists have explored a variety of ways of sampling occurrences while ensuring that those occurrences are not dominated by a small number of very extensive lists, at the expense of the greater geographical dispersion of samples that one would get using rarefaction by list, or by published reference (see *Alroy et al., 2008*, for an example). For instance, the probability of sampling occurrences from larger lists may be down-weighted, relative to those from smaller lists, thus increasing the probability that a standardized sample of occurrences is drawn over a broader geographical area. A variety of such algorithms have been tried, which essentially weight alpha, beta, and gamma (i.e., local, among-habitat, and among-region) diversity differently. For example, one of the more commonly used methods assumes that alpha diversity does not change through time. Most recently, more complicated approaches have been proposed. For instance, in “quorum subsampling,” each species is assigned a value based on the frequency of its occurrences in the original

Figure 3 A graphical illustration of rarefaction by list. In this case, an entire paleontological sample is drawn at random from the population of samples that constitute the data set, and rarefied diversity is the total number of unique taxa contained in those lists for a given number of samples drawn. In this figure, the rarefied diversity after two samples have been chosen at random is six species (A, B, E, F, G, and H).

data. As new taxa appear in the subsample, a cumulative sum of these frequencies is updated until some specified level of coverage is achieved (*Alroy, 2010*).

Paleontologists have typically been very cautious in their interpretation of rarefied diversities. There is a reason for this caution: the biological meaning of a standardized diversity measurement (or a relationship between two standardized diversity measures) is, in most cases, unclear. The interpretation offered by Hurlburt (described earlier) is appropriate only when (1) the sampling protocol described in the first paragraph of this section has been followed or (2) each occurrence of a taxon is a truly independent, random sample from the habitat about which one wishes to make inferences. Generally, neither is true for large-scale paleobiological diversity estimates, because paleontologists use a wide variety of sampling methods and sampling effort has not been distributed randomly. However, there have been some recent advances in this area, particularly recent work initiated by Bush (e.g., *Bush et al., 2004*) that attempts to determine, from first principles, how different sampling standardization methods respond to different patterns of alpha, beta, and gamma diversity. Even where such insights are unavailable, however, rarefaction can provide useful information. In particular, discrepancies between rarefied and overall diversity patterns indicate where marked increases or decreases in apparent diversity are likely to be artifacts of sampling.

Nonparametric Estimates

In contrast to sampling standardization, a variety of methods attempt to estimate the actual underlying taxonomic richness in a particular interval have been explored, although these techniques are far less prevalent than sampling standardization. Among the most common (although typically not applied at very large spatial scales) are nonparametric methods that utilize the frequency distribution of fossil occurrences for a particular interval of time. That is, the raw material for

the diversity estimate is the number of taxa occurring in only one sample, f_1 , the number occurring in two samples, f_2 , and so on, as well as the total number of occurrences in all samples.

Burnham and Overton (1979) utilized a statistical approach known as the jackknife. The mathematics of the derivations are too complex to review here, but with this approach they obtained a series of possible estimators. The simplest of these utilizes only the number of samples and the number of taxa occurring in only one sample:

$$\hat{D}_1 = D_{\text{obs}} + f_1 \frac{k-1}{k}, \quad [1]$$

where $\hat{D}_1$ is the first-order jackknife estimate of diversity, D_{obs} is the number of distinct taxa appearing in the sample, f_1 is the number of taxa occurring in exactly one sample, and k is the number of samples. They developed additional estimators by incorporating the number of taxa occurring in more than one sample (for instance, their second-order jackknife uses the number of taxa appearing in exactly two samples, as well as the number appearing in just one). Nichols and Pollock (1983) applied these models to a molluscan dataset from the Middle Miocene (16–12 Ma) of Denmark. They found that, even under a relatively intensive sampling regime, sampled diversity was as much as 30% lower than estimated diversity.

An alternative model, proposed by Chao (1987), uses the number of taxa occurring in either exactly one or exactly two samples:

$$S_2 = D_{\text{obs}} + \frac{f_1^2}{2f_2} \quad [2]$$

Wing and DiMichele (1995) used this estimator, usually termed “Chao-2,” to compare regional vegetation diversity in the late Paleozoic and early Cenozoic for North American river and delta floodplains. Somewhat surprisingly, they found similar biodiversity levels during the two periods for these regions, despite the markedly higher apparent diversities for the latter interval at the global level. The same formula has also been applied to estimate local diversity, but with the number of individuals representing each taxon in a single sample used rather than the frequency of occurrences in a set of multiple samples. That is, f_1 is the number of taxa represented by only one individual in a sample, f_2 is the number represented by two individuals, and so on. Wing and DiMichele (1995) used this approach to examine local vegetation biodiversities in the Paleozoic and Cenozoic floodplain data set discussed previously. They found that, on average, local diversity in the late Paleozoic was similar to local diversity in the early Cenozoic. This was consistent with their findings for regional diversity using the Chao-2 estimator. However, they did find greater variation in diversity levels among sites in the Cenozoic; in particular, the most diverse Cenozoic sites were much more diverse than the most diverse Paleozoic sites.

Yet another approach, developed by Chao and Lee (1992), utilizes the entire frequency distribution of occurrences in a set of samples, rather than just the number occurring in only one or a few samples. Wang and Dodson (2006) used this method to estimate that vertebrate paleontologists have discovered and

named only ~29% of an estimated total of ~1850 nonavian dinosaur genera. Anderson *et al.* (1996) estimated South African late Triassic (228–200 Ma) plant and insect diversities with this method.

These approaches have some advantages over sampling standardization. Perhaps foremost of these is that it is clear what is being estimated – the number of taxa in the sampling universe from which the occurrences have come. Secondly, the estimators are explicitly derived from a set of statistical assumptions, so it is possible to quantitatively assess how well those assumptions are met. Unfortunately, some of these assumptions are violated in fossil data, often quite severely, so they are likely to produce biased estimates in many applications. For instance, the jackknife and Chao estimators assume that each taxon has an equal probability of occurring in each sample. That is, taxon A may have a different probability of being present in a sample than taxon B, but that taxon-specific probability is the same for every sample. This assumption may be violated if samples differ in extent or quality. However, even if great care is taken to minimize this problem, the assumption may still be violated. For instance, if relative abundances of particular taxa differed among sampling locations, then the associated relative probabilities of sampling may differ accordingly.

Parametric Estimates

Nonparametric methods seek to make minimal assumptions about the true underlying probability distribution of abundance or occurrences. However, parametric approaches assume that these distributions follow a particular mathematical form, they estimate the parameters of this distribution for a particular sample or set of samples (hence the term parametric), and they then use those parameter estimates to infer the fraction of species predicted not to be sampled at all. Various distributions have been proposed as good fits to fossil data, and it has been suggested that the best fit distributions may even change through time reflecting ecological changes in the biosphere. In one such case, such a fit has been used to estimate unsampled diversity. The particular probability distribution used was the Generalized Inverse Gaussian-Poisson (GIGP) distribution. Anderson *et al.* (1996) fitted this model to plant and insect data mentioned in the previous section. They used these estimates to argue that late Triassic plant and insect diversity in the sampled habitats was comparable to those of the present day, again in contrast to apparent global diversity patterns, which record increasing biodiversity levels through time.

The primary limitation of this approach is that it assumes that the underlying frequency distribution of occurrences follows a particular statistical distribution. As a general rule, parametric methods are more precise than nonparametric analogs when the assumptions about the underlying distribution are met. When they are not, however, the estimates can be very inaccurate. Another limitation, shared by the nonparametric estimates, is that the uncertainty associated with the estimated diversity increases as the proportion of unsampled taxa increases. That is, when the probability of a taxon appearing in a sample is low on average (or when

there are few samples), the estimates are especially prone to error. For this reason, the fact that a method works well as an estimate of present-day diversity does not necessarily mean that it will work well when applied to the fossil record, except perhaps where that record is unusually complete.

In ecology, parametric models have been used to infer local and regional diversity from observed distributions of occurrences or abundance, sometimes with good results. One potential problem with the application of such methods to the fossil record is that differences among taxa in their probability of entering the fossil record, and subsequent loss of fossiliferous rock (at rates that may vary among regions and through time), may make distributions of fossil occurrences very different from distributions of occurrences of living organisms. However, to date, models that are commonly used by ecologists, such as the lognormal and the gamma distribution, have yet to be applied to the fossil record.

Turnover-Based Estimates

Paleontologists typically break taxa down into five categories relative to their occurrence before, in, and after the time interval in question: (1) those sampled before, in and after; (2) those sampled before and after (but not in); (3) those sampled before and in (but not after); (4) those sampled in and after (but not before); (5) those sampled only in the interval (not before or after). In traditional stratigraphic range based estimates of diversity, all of these taxa contribute to the diversity in the time interval, although taxa only occurring in a single time interval are often removed from paleontological analyses, because such “singletons” are particularly sensitive to between-interval variation in sampling intensity. An alternative, known as “boundary crosser” estimates of diversity, count diversity at interval boundaries, rather than within intervals. For instance, diversity at the bottom of an interval includes all of the taxa crossing the bottom boundary (found sometime before and after the boundary, including those not actually sampled in the interval itself). Both traditional and boundary-crosser approaches have been widely used in paleontological analyses, and several other counting methods have been used occasionally as well.

It has been suggested that better estimates of diversity (along with rates of origination and extinction) can be obtained by only counting taxa that occur in two consecutive intervals (two timers), three consecutive intervals (three timers), or the first and third but not the second interval (part timers). Although *ad hoc*, these data selection criteria appear to be relatively robust to the biases typically associated with fossil data. Thus, while these counting methods underestimate diversity even more than standard range-through approaches, they are likely to be more robust as measures of relative diversity across multiple time intervals.

In the mid-1980s, Nichols and Pollock (1983) proposed that the information contained in presence-absence sequences in the fossil record should be used more systematically to estimate diversity. Specifically, they proposed that “open-population” statistical methods used to estimate abundances (along with birth and death rates) from

capture-recapture data in population biology could be adapted, by analogy, to estimate taxonomic diversity (along with origination and extinction rates – births and deaths of taxa) in the fossil record. When one conducts an “open-population” capture-recapture study, individual organisms are captured during discrete sampling occasions over a period of time. Each individual captured is given a unique mark, so that its capture history can be constructed. That is, if one constructs a matrix, the columns j of which represent different sampling occasions and the rows i of which correspond to each individual captured at least once, then each element a_{ij} in the matrix will be either 1 or 0, indicating whether individual i was captured on occasion j . Similarly, fossil data are collected during discrete sampling periods, and one can simply list the taxa sampled in each interval. In this case, the matrix elements a_{ij} are 1 or 0 according to whether taxon i was found in interval j . In this context, taxonomic diversity (the total number of distinct taxa) is analogous to population size (the total number of distinct individuals). Thus, each species’ sampling history is a sequence of presences and absences. This set of sampling histories can be used to estimate probabilities of sampling, origination, and extinction, and to estimate total taxonomic diversity, using standard statistical theory.

Like nonparametric and parametric diversity estimates that utilize replicate samples within an interval of time, these turnover-based methods make assumptions that are rarely fully met by fossil data, and it is not always clear which results are robust to violations of assumptions and which are not. However, a major advantage of these approaches over sampling standardization approaches is that it is possible to test for, and estimate the magnitude of, violations of those assumptions. When Nichols applied a turnover-based estimate to late Eocene (37–34 Ma) mammals from the Big Horn Basin, Wyoming, goodness of fit statistics indicated rejection of the model. However, when applied to Middle Miocene molluscan diversity, the model provided an adequate fit. Similarly, goodness of fit testing was used by Connolly and Miller (2001) to show that violation of assumptions was unlikely to have severe effects on estimates of origination and extinction (in other words, that the uncertainty in the estimates was likely to be fairly large, relative to any biases due to assumption violations).

Some of the most questionable assumptions in turnover-based methods involve the assumption that probabilities of origination, extinction, and sampling are constant for all taxa that are grouped together in an analysis. To minimize the potential biases associated with violations of these assumptions, researchers have adopted several approaches. One is to divide taxa into subgroups believed to have different sampling or evolutionary turnover rates, and estimate parameters for them separately. An alternative is to relax that assumption, and use characteristics of individual taxa believed to be positively or negatively correlated with sampling, origination, or extinction rates, and to estimate the parameters of that relationship. For instance, Connolly and Miller (2001) allowed sampling probabilities to differ among Ordovician (488–461 Ma) marine invertebrate genera according to differences in the apparent geographical and ecological distribution of those genera.

Conclusions

As we have seen, many features of the fossil record make assessing diversity trends difficult. Some of these difficulties can be eased, at least in principle. For instance, unequal distribution of sampling effort by paleontologists can be reduced by emphasizing undersampled regions and strata in future fieldwork. Similarly, the expanding palette of tools for dating fossils and their surrounding sediments, their increasing precision, and the development of more robust statistical methods for chronostratigraphic correlation is progressively improving the fossil record's temporal accuracy and precision. However, some problems are less tractable. For instance, fossiliferous rock is progressively lost as it ages. Thus, the fossil records of large regions (and thus the record of biodiversity in the associated habitats) may simply not exist. This problem is particularly acute for older time intervals. Similarly, organisms in some habitats are simply less likely to be preserved than organisms in others, and those habitats will thus have poorer records of their biodiversity history.

Several approaches have been used to account for these sampling effects in the estimation of diversity or (in the case of rarefaction) to minimize the effects of variation in sampling on estimates of relative diversity. All of these approaches were originally designed to estimate local diversity; thus, their application to regional and global patterns is problematic, and workers have interpreted results cautiously. Nevertheless, these results can sometimes be used to eliminate some explanations for particular biodiversity trends. For instance, Raup's use of rarefaction confirmed that the increased diversity of echinoids through time was not solely due to the greater number of paleontological samples available for younger strata. When the results of these approaches differ from one another, or from diversity trends apparent from the fossil record in its entirety, however, things become complicated. Do the estimates indeed account for sampling effects and reveal true diversity trends, or does violation of model assumptions render the estimated trends even less reliable than the uncorrected diversity trends they are intended to improve?

The future of diversity estimation will no doubt involve considerable effort on several fronts. One promising approach is to apply several methods, then identify biodiversity trends that are robust to these alternative methods. Another is to investigate directly how different estimates are biased when particular assumptions are violated, then devise means of minimizing these biases. Diversity estimation methods that have not yet been applied to the fossil record may be incorporated into the paleobiological research program, and new estimates will undoubtedly be forthcoming as well. Nonparametric methods based on the frequency distribution of occurrences have been identified as a promising area for further progress by many biostatisticians, so increasingly robust metrics are likely to become available. Parametric estimates of diversity may also come into greater use, as ecologists

increase their understanding of the shapes of frequency distributions of abundance and occurrence over different scales of time and space. The development of computationally intensive methods of model fitting may allow the use of "mixture models," which would allow sampling, origination, and extinction rates to vary randomly among taxa in turnover-based statistical models, rather than being assumed constant or specified to vary only in response to particular explanatory variables. In recent decades, quantitative approaches have been rapidly growing in popularity and sophistication among paleobiologists. This movement is likely to produce an increasingly clear picture of the history of biodiversity.

Glossary

Alpha diversity Diversity of species within a single habitat.

Beta diversity Measure of the rate and extent of change in species along a given habitat or physiographic gradient.

Disparity Range of diverse morphological architectures present in higher taxa such as classes, phyla, and kingdoms; it is used to explain the origins and maintenance of this diversity of life-forms and body plans.

Taxonomic richness Number of species, genera, and families from a given time period or fossil excavation.

Biodiversity in the Fossil Record

There are two distinctive though related aspects to paleobiodiversity studies. One approach focuses on the number of taxa present during a certain geologic time, or over a certain geologic time span. The taxonomic categories involved are usually species, genera, or families, and this sort of diversity is commonly termed taxonomic *richness*. The ultimate aim of most such studies is to understand and explain the origin and maintenance of patterns of species richness in space and time; when genera or families are used it is usually as proxies for species. The evolution of species richness has been studied since Darwin's time and continues to be a highly productive area of research. The second aspect deals with diversity, not of numbers of species, but of different types of organisms. The taxonomic categories involved are the higher ones, such as kingdoms, phyla, and classes, and the aim is to understand and explain the origins and maintenance of *disparity*—the range of diverse morphological architectures that is present. The major patterns of disparity over geologic time have been described, chiefly using taxonomic categories, as proxies for morphological distance. However, the evolution of that disparity has received much less attention than the evolution of richness, partly because it was thought that disparity could be explained by extrapolation from the processes that create richness. With the rise of molecular developmental studies, however, the genetic basis for disparity is becoming understood, and it has become possible to decouple studies of the origin of disparity from those of richness.

The ecological regulation of local biodiversity is not well understood, but empirical patterns of species distributions and richnesses indicate some of the factors governing species accommodation on regional and global scales. These large scales are of particular importance to tracing biodiversity through time. A basic measure of species richness is *alpha diversity*, the number of species found at a given locality or in a single sample. A second sort of species richness, *beta diversity*, is a measure of the additional species that are found at a second locality or in a second sample. Alpha diversity was taken to indicate the amount of species packing (reflecting ecological niche partitioning) at a locality, and beta diversity to indicate the extent of habitat differences between localities. In practice,

however, different species are found at a given locality at different times, varying with season, weather, or other factors that affect successful reproduction or colonization at the locality. Alpha diversity can therefore vary significantly from time to time, in which case beta diversity is affected as well.

The global environment is quite heterogeneous, a mosaic of habitats separated by gentle gradients in some places and by sharp boundaries in others and further broken into disjunct regions, such as different continental masses or remote islands. Beta diversity will vary according to whether two samples are from adjoining areas within the same general habitat type (i.e., represent the same biotic community), or are from distinctive habitat types (represent different communities), or are from distinctive climatic or physically disjunct regions (represent different biotic provinces). Though beta diversity is sensitive to differences among samples within a community, it is not as useful a measure between communities; rather, a more appropriate measure is the number of species added as entire communities are combined—a sort of super beta diversity. To capture global biodiversity patterns, a hierarchy of beta-type measures is required; differences between bioprovinces can be evaluated by the numbers of species added when combining one entire bioprovince with the next, or similar evaluations can evaluate differences between bioprovinces can be made between entire realms. The pattern of environmental heterogeneity in the world has varied continuously over geologic time, thus affecting the pattern of accommodation of biodiversity.

Evolution and Biodiversity

Richness

Speciation is produced by isolation of populations, severing the flow of genes between them and permitting the evolution of differences in their features, underlain by differences in genes, gene frequencies, and gene organizations that arise between the populations. Once sister population crosses are unable to produce fertile offspring, speciation is complete. Environments favoring more isolation among populations are therefore more likely to produce rich biotas, other things

being equal. A world broken into many continents favors global species richness, with a nearly separate biota on each continent. A continental landscape consisting of a great variety of climates and habitat types favors more species richness than does a monotonous landscape, for species tend to become well adapted to particular habitats, and the more habitat types available, the more species. A landscape in which any given habitat type is scattered among other types, which therefore provide barriers to gene flow, favors more species richness than a landscape where each habitat type occurs in a large tract. In short, environmental heterogeneity clearly promotes isolation and therefore species richness through speciation. Other factors also promote speciation, but they are not so clear nor so well understood. For example, low-latitude, tropical regions hold many more species than midlatitude temperate regions, and these latter hold more than high-latitude arctic/antarctic regions, but the mechanisms that link the obvious climatic differences to this latitudinal gradient in species richness are not yet understood. It is clear that the reduction of environmental heterogeneity by human activities is lowering the capacity of the globe to support species.

Disparity

The genetic differences producing morphological disparity are not based so much on differences in genes and gene frequencies as on gene organization. Individuals belonging to different higher taxa, such as phyla, differ from their very early stages, producing different adult body plans as they develop. In animals, the developmental regulatory genes that are responsible for organizing the many disparate body plans are surprisingly similar. The animal phyla originated over half a billion years ago, so similarities in those developmental control genes have been conserved since that time. Even members of other kingdoms, such as fungi and plants, share some similarities with animals in their developmental control genes, which therefore have been conserved for over a billion years. Some key developmental genes have been found in all phyla that have been investigated, though they may play a variety of roles. These genes are responsible for regulating still other genes. The regulatory genes govern cascades of gene expression that mediate cellular differentiation and organogenesis, the hallmarks of multicellular body plans, and control the final body architecture. The evolution of disparity has involved the evolution of these basic developmental control systems. Thus, although the genes are similar among phyla, many of the gene expression pathways are different within each phylum and class and so produce distinctive body plans.

In animals, the use of genes that mediate the development of numbers of cell types and morphologies seems to have originated in a spongelike organism. Animal genomes contain two to three times as many genes as most unicellular protists, suggesting that one or more early, massive gene duplication event(s) provided the genetic resources that were necessary to regulate the development of complex morphologies. Vertebrates have approximately four times as many genes as an average invertebrate, suggesting that some massive gene duplication events in early chordate lineages provided a genome of the requisite size to permit the evolution of the very

complex vertebrate bodies. Regulatory genetic systems have evolved in land plants as well, quite independently, mediating the disparity found in plant anatomy, but as yet these systems are not as well known as those of animals.

Capturing Fossil Biodiversities

Problems of Sampling Fossil Biodiversity

It is not easy to become a fossil; the remains of only an exceedingly small fraction of all the organisms that have lived have survived to provide information on the nature of life through geologic time. Therefore we must treat the fossil record of biodiversity as a huge sampling problem. One approach would be to estimate how many samples from how many places it would take to adequately represent present biodiversity, and then to compare this ideal sampling pattern with the sorts of fossil samples with which nature has presented us. To estimate today's biodiversity we would need to sample each community in each province on each continent in each major realm, such as terrestrial plains and mountains, continental shelves, and each major oceanic water mass and deep-sea region. We would not have to find every last species, but we would have to understand the patterns of species' distributions well enough to calculate biodiversity from our samples. Although valiant attempts have been made, the problem is so large that estimates of modern biodiversity are not closely constrained. Assessing fossil samples is not easy either. We need to know how densely the biota has been sampled regionally and ecologically by nature in presenting us with the fossil assemblages. And for a given fossil assemblage, we must estimate how completely the living biota was sampled, without knowing how diverse it was in the first place. We also need to know how different ancient biotas were from region to region, for it is not uncommon for large regions to lack fossils for given time periods, and their diversities must then be estimated from assumptions about global patterns. Finally, we must be able to estimate the temporal density of the fossil record and make allowances for intervals of time that lack records.

Completeness of the Rock Record

The rocks from which fossils have been recovered are nearly all exposed on land and have therefore been subjected to erosion, and many fossiliferous formations have been stripped away and lost. The first question to ask when reconstructing fossil biodiversities is how much of the original rock record remains. The completeness of a sequence of rocks is independent of its age, relating rather to its depositional history. In general, sedimentary sequences contain many small gaps but increasingly fewer gaps of longer durations. For a given sedimentary sequence, then, fossil taxa with very short geologic ranges may have been present only during a gap, whereas longer-ranging forms can "jump" most gaps and may be captured as fossils. Fortunately, the gaps in one region are commonly represented by sediments elsewhere, though a few periods of time are poorly represented in most regions. For example, few marine sediments are preserved on continents from times when sea

levels were particularly low, such as at the end of the Permian and beginning of the Triassic periods.

Terrestrial sedimentary rocks, deposited as they are above sea level, are subjected to very active processes of erosion, which remove much of the sediment in rivers or in winds and deliver it to the sea. Preservation of terrestrial formations is thus restricted chiefly to downwarped epicontinental basins or interior continental platforms, where there is some protection from the main erosional forces. Such settings tend to be more localized and geologically shorter-lived than nearshore marine sites. Furthermore, terrestrial animal remains are also exposed to decay and erosion in the subaerial environment and tend to be destroyed more easily than the shells of marine forms. Thus, terrestrial rock sequences are less complete than marine ones, and terrestrial animals are not as well sampled by the fossil record as marine animals.

Incompleteness of the Fossil Record

Organisms differ greatly in their potential for preservation as fossils. In general, entirely soft-bodied, or small, or rare, or geographically restricted species of short durations have fewer opportunities for preservation than their opposites: a large, abundant, widespread species that lived for many millions of years and has a very durable skeleton is most likely to be represented by fossils. Some phyla, such as Mollusca (clams and snails, etc.) are well represented in marine sediments, whereas others, such as Platyhelminthes (flatworms), though at least as old as the Mollusca and quite rich in species, have left no recognized body fossils. The biodiversity of the living biotas from which fossil assemblages are recruited must usually have been considerably greater than the numbers of fossil taxa that are found. However, it seems that most species with durable skeletons are in fact originally captured in sediments. For example, a study of fossilization of living species of marine bivalves (Mollusca) of the Californian bioprovince found that about 80% of the species, 84% of the genera, and 90% of the families were represented by fossils in sediments of Pleistocene age (the last 1.6 million years). As expected, the missing species were small, thin-shelled, and rare forms, and the missing genera and families were made up of such species.

In richness studies of taxa with high preservation potentials, such as shelled mollusks, fossil assemblages actually have an advantage over samples of the living biota. The fossils are usually time-averaged, that is, they represent the accumulation at a given locality of many generations and may include individuals of species that have occupied the region for only some fraction of the time represented. Thus, a fossil assemblage can sample the species richness that was found in a given area far better than a sample of alpha diversity in a living community. The fossils represent a sampling through time, often over hundreds to thousands of years.

Foote and Sepkoski (1999) devised a method that estimates the probability of preservation of fossil higher taxa from a sort of frequency distribution of the observed geologic range lengths of their members. When such an estimate is made for marine bivalves (clams), the probability of preservation of a genus within a stratigraphic interval representing about 5 million years is around 50% (Figure 1). The bivalve faunas

preserved in the sediments have been significantly degraded. Although some elements of the fossil faunas may have been destroyed by dissolution within the sediments, it seems likely that most of the missing genera were originally present in sediments that were then either removed during intervals of erosion or are not now exposed for collection and study. In other words, although fossils commonly represent a good sample of living associations of easily preservable taxa, not enough such associations are preserved to directly count ancient diversities over lengthy intervals of geologic time.

The completeness of the record of a number of other higher taxa is given in Figure 1, where the probability of their generic preservation is plotted against the proportion of the living families that have a fossil record. There are two groups that deviate from the general trend. The Cephalopoda (Mollusca) fall well above the trend because they are represented by rich fossil assemblages of extinct higher taxa and have few living representatives. By contrast, Chondrichthyes (Chordata) fall well below the trend because their living families have a good fossil record, chiefly of teeth found in relatively young sediments, but the earlier fossil genera, represented by bodies, are mostly known only from single localities and thus have low preservation potentials. Thus the two outliers are readily explained, and the correlation otherwise evident between these totally independent data sets suggests that they are reasonably accurate. Because the marine sedimentary rocks of continental shelves combine high completeness and availability, the marine invertebrates with the highest preservation potentials provide the longest, most complete fossil record of any major groups of organisms.

In establishing the geologic range of a fossil taxon, it is almost certain that we have not found the earliest members to evolve or the last individuals to become extinct, because the fossil record is so incomplete. It is possible, however, to judge the probable extent of a taxon's range beyond its actual record by how commonly it is found between its first and last occurrences: if it occurs rather continuously within its known range, then when it disappears it is likely to be absent; if it occurs rarely, then it may have existed well before we see it and continued to exist well after our last record. The number of a taxon's occurrences in a given time interval thus permits a statistical estimate of the likely extent of its true geologic range. By taking account the observed preservation potentials of a taxon, estimates of the numbers of that taxon present in a given interval can be augmented by granting range extensions beyond the fossil occurrences. Corrections of this sort will produce better approximations of the richness within geologic intervals than the raw numbers of fossil taxa in collections.

Partial Remedies for the Spotty Fossil Biodiversity Record

The taxonomic hierarchy, based on Linnaean principles, produces many paraphyletic taxa, but it is useful for purposes of biodiversity reconstruction. Even within taxa with the highest preservation potentials, a large proportion have been lost to erosion and other factors. Genera, on the other hand, contain on the average several species, so that a genus is usually more widespread, occurs in more environments, and contains many more individuals than any one of its species. As a

Figure 1 Two measures of completeness for taxa of marine animals: the vertical scale is the calculated probability of the preservation of a genus of the taxa per stratigraphic interval; the horizontal scale is the proportion of living families of the taxa with a fossil record (a measure of the preservation potential of the taxa). There are two points (boxes) for each taxon because two different timescales (with different bins) were used to evaluate binning biases. The significant correlation of these two measures indicates that the estimated completenesses are generally accurate. The Cephalopoda and Chondrichthyes are outliers; see text for discussion. Reprinted from Foote M and Sepkoski Jr. JJ (1999) Absolute measures of the completeness of the fossil record. *Nature* 398: 415, with permission from Nature.

consequence, the fossil representation of genera is more complete than that of species. Families usually include several genera and so are even more completely represented as fossils. Thus by compiling biodiversity data on the generic level, one produces a significantly more complete and somewhat more accurate record than is possible at the species level, and the record at the family level is even better.

There is a price for this taxonomic remedy. The lower levels of taxonomic biodiversity are the more volatile through time, being more sensitive to the environmental changes that affect biodiversity. For example, a wave of extinction may decimate a biota at the species level, but to be recorded in a compilation of family diversity an extinction must extirpate every last species of a family. A small extinction wave might not even be noticed at the family level, considering that fossil data are rather noisy anyway. Of course the time of an extinction, whether recorded at the family, generic, or species level, will be registered in precisely the same place on the geologic time-scale. Because species contain reproducing populations, they are in direct ecological contact with environmental parameters, and the volatility of their richness is the most sensitive measure of environmental changes. Higher taxa record the outcome of environmental change more indirectly, that is,

when their species first appear, or when all of them disappear from the record. Nevertheless, their behavior in the face of environmental change presumably reflects the broad similarities in physiological and behavioral responses of their species, inherited from common ancestral species. While generic and family biodiversities can make quite useful proxies for species diversity in the fossil record, they are in fact measuring different features, and this should be taken into account in interpretations of fossil richness.

Most individual fossil samples represent a particular ecological community, perhaps somewhat intermixed with rare species that are chiefly found in other communities, where they are common. In some cases, though, the samples represent mixtures of common faunal elements that represent different communities but that lived in close proximity. It is sometimes possible to establish biodiversities for meta-communities by taking many samples of similar, approximately contemporaneous fossil assemblages at different localities throughout a region, using the rule that species that occur together most often as fossils are most likely to have lived together. Because two fossil localities are likely to vary in composition even if drawn from the same parental biota, an increasingly full picture of regional biodiversity is gained

when numbers of localities are pooled. Such studies can lead to understanding the gross diversity patterns among biotic provinces. Finally, sampling of approximately contemporaneous localities can be made at the global level, in this way providing a sample of global biodiversity for the realm(s) involved.

Because most fossil localities are not directly dated by the more accurate radiometric techniques, correlation between them can only be approximate, particularly when the fossil assemblages represent different communities or provinces. This difficulty can be mitigated by using fairly coarse time units, within which most fossil localities can be placed with some confidence. Global biodiversity studies using families and genera usually employ temporal bins of from 5 to 8 million years in duration. Some studies have used geologically based time subdivisions, such as Stages; in these cases the diversity must be normalized to the differing Stage lengths.

The various approaches to help in overcoming the incompleteness of the fossil record yield binned samples of adequate size and quality to establish general levels and trends of biodiversity within well-skeletonized groups on global scales over long periods of time. The times of major diversifications or extinctions and periods of high and low biodiversities are captured by such data. Changes in the relative dominance of different major clades are also clearly demonstrated. However, the price for binning is that fine details of diversity changes are lost. Yet preliminary studies indicate that the generic record captures the same events as the family record and indeed is more sensitive to diversity changes. Furthermore, increasingly accurate dating techniques are permitting the use of ever-shorter time intervals. These ongoing refinements have confirmed the general trends described from the coarser data, while permitting the recovery of more detailed diversity information that reflects more closely the history of species richness.

Microbial Diversity of the Archaean and Proterozoic Eras

The earliest rocks known on earth date to about 4.6 billion years ago. The earliest eras in earth history, long thought to be barren of indications of life, were named the Archaean (about 4.6–2.5 billion years ago) and the Proterozoic (about 2.5 billion–543 million years ago). The most recent era was named the Phanerozoic (visible life) because it contained a fossil record. However, microbial fossils have now been found to date well back into the Archaean. The earliest are filamentous prokaryotic microbes resembling cyanobacteria ("blue-green algae"), recovered from chert beds that are over 3.5 billion years old. There are a few other Archaean records of microbial fossils that may be from other bacterial groups, representing both benthic and planktonic realms. However, bacteria and archaea have such extremely low preservation potentials that it is impossible to reconstruct their history of richness from fossil evidence. According to molecular phylogenies, a number of major bacterial branches, equivalent at least to phyla in a hierarchical system, arose before the cyanobacteria. It appears likely that there was a rapid early diversification within the bacterial and, probably, archaeal

domains that produced a highly disparate microbiota well over 3 billion years ago. Considering the way in which lineages branch during evolutionary diversifications, it is likely that the microbiota was quite rich during much of Archaean and Proterozoic times. Recorded fossil diversity is much greater in the Proterozoic, but sampling is much better in rocks of that age and the recorded fossil richness simply tends to correlate with the number of formations and samples studied. One exception is in the latest Proterozoic, when sampling is highest but when the richness of fossil microbiotas declines, suggesting a real diversity drop at that time. The fossil record of richness of the Proterozoic microbiota is given in **Figure 2**.

Unicellular fossils belonging to the Eukarya are difficult to separate from those of other domains. Relatively large fossil algal ribbons (1 m long, 2 mm in diameter) about 2.1 billion years of age are likely to be the first known eukaryotes. It is possible that Eukarya evolved during the Archaean. The best Proterozoic records of unicellular Eukarya are of spheroidal plankters with organic walls, sufficiently tough to be preserved in some quantity. They increase in number, richness, and morphological complexity throughout the Proterozoic. As noted earlier, great bacterial disparity is likely to have been achieved in the Archaean, and the major richness trend may be attributed chiefly to an improving fossil record rather than to increased biodiversity.

Phanerozoic Marine Biodiversity

Neoproterozoic Animals

The record of metazoan fossils dates from at least 570 and possibly 600 million years ago, in the late Proterozoic (the "Neoproterozoic"), but it has proven to be very difficult to relate those early fossils to living groups, which first appear near the beginning of the Phanerozoic. There are two chief modes of fossilization: trace fossils, which are trails, burrows, and similar structures left in sediments by animal activities; and body fossils, which register the gross morphology of the animals. Most Proterozoic body fossils are restricted to body impressions, skeletons being absent until latest Neoproterozoic time. The early trace fossils are simple curved trails, and though traces become increasingly complex and diverse as time passes, they remain small throughout the Neoproterozoic, mostly 1 mm or less in width, though a few range to 5 mm. The early body fossil impressions (the "Vendian" or "Ediacaran" fauna) are chiefly of frondose and discoidal organisms that are large (some reach 1 m) and bear a general resemblance to cnidarians, although they differ from living forms in important structural details. Ediacaran faunas also include rare sponges and a few forms that resemble bilateral animals but that cannot be assigned to any living group. Estimating the living diversity of Neoproterozoic times from these fossils is difficult; body fossils of the trace-makers, for example, are not known, and many kinds of organisms can leave a given type of trace fossil. When body fossils appear during the Cambrian (see the following section), traces become larger (some are centimeters wide), much more varied, and more common. Therefore the best guess for

Figure 2 Species richness of several groups of unicellular microfossils as represented in Proterozoic sediments. The morphologic categories to the left of the heavy dashed line are presumptive Bacteria; those to the right are Eukarya. The record is unlikely to mirror the history of either richness or disparity, although the decline late in Proterozoic time may be real. Reprinted with permission from Schopf JW and Klein C (eds.) (1992) *The Proterozoic Biosphere*. Cambridge, UK: Cambridge University Press.

Neoproterozoic animal diversity is that it was lower than that of the Cambrian, beginning sometime before 570 million years ago (Ma), possibly tens to hundreds of millions of years earlier. This guess is likely to be correct as far as body plan disparity is concerned, but it remains possible that Neoproterozoic seas supported a rather high richness of species that had such low preservation potential that they have not yet come to light.

The Cambrian Explosion Establishes Metazoan Disparity

About 543 Ma there was a notable increase in the complexity, sizes, and abundances of trace fossils, one of which (*Triptichnus*) marks the basal Cambrian boundary by international agreement. Rare, minute, mineralized skeletons of uncertain affinities had appeared just prior to the first appearance of *Triptichnus*, and continued to appear in increasing kinds and numbers, along with an increasing trace diversity, in younger rocks. At about 530 Ma the earliest undoubted skeletons of living animal groups appeared and, during the next 10 million years or so, 11 animal phyla made their first appearances, a period known as the “Cambrian explosion” because of the geologically sudden appearance of diverse, abundant skeletal remains. Invertebrate skeletons are then continuously present for the remainder of geologic time. Among the body plans to appear during the explosion are complex representatives of all major animal clades, including annelids, arthropods, and chordates (Figure 3). Judging from the phylogenetic tree of animals, all living phyla had originated by the close of this interval, although some living phyla with low preservation potentials are still completely unknown as fossils.

Many of the explosion animals include features that are not present in their living allies, and thus extend the known morphological ranges of their clades. Some of these forms

have such distinctive body plans that they are considered to be phyla of their own, whereas others can be nested within living phyla but not within living classes. These forms indicate that the disparity among the body plans of Early Cambrian animals was at least as great as it is today. For example, the relatively few Cambrian arthropod taxa are just as morphologically disparate as are living arthropods, which have had the benefit of over half a billion years of subsequent evolution and consist of million of species today. Thus disparity and richness are evolutionarily decoupled. The Early Cambrian burst of disparity in the fossil record suggests that there was relatively rapid evolution of the developmental regulatory gene systems at that time.

Phanerozoic Diversity Patterns in the Marine Environment

Standing Diversity of Marine Invertebrates

The combination of completeness, disparity, richness, and duration of the marine fossil record is superior to that of other realms, especially for marine invertebrates, and thus is best suited as an introduction to major diversity patterns. Figures 4 and 5 depict the overall pattern of family richness for marine animals, almost entirely shallow-water (continental shelf depth) forms. It is likely that the range of body plan disparity declined somewhat after the Cambrian, and probably showed a significant drop and then a recovery following the Permian–Triassic extinction, but there are no data that incorporate the entire marine fauna. However, Jack Sepkoski has compiled an excellent data set on family richness, which has certainly varied significantly.

During the Cambrian, family richness rose abruptly and seemed to be reaching a plateau as the period ended. However, the Ordovician witnessed a dramatic increase in family richness, which reached a plateau near 400 families by the end of

Figure 4 Marine animal family richness known from the fossil record. Geologic period abbreviations are as in **Figure 3**. Major faunas are labeled €, (Cambrian Fauna), Pz (Paleozoic Fauna), and Md (Modern Fauna). Shaded area at top of curve indicates animals that lack durable skeletons. Reprinted with permission from Sepkoski Jr. JJ and Miller AI (1985) *Evolutionary faunas and the distribution of Paleozoic marine communities in space and time*. In: Valentine (ed.) *Phanerozoic Diversity Patterns: Profiles in Macroevolution*, pp. 153–190. Princeton, NJ: Princeton University Press.

fish clades in Late Paleozoic seas. Also arising at least by Early Devonian time was a clade, the osteichthyes or bony fishes, which was of secondary importance during the Paleozoic but came to be the most richly diverse vertebrates in the sea during the Mesozoic and quite dominate marine vertebrate faunas today. Thus the history of marine fishes can be summed up as beginning modestly in the Cambrian and finally achieving significant disparity during Silurian and perhaps Early Devonian radiations that established most major groups, which then waxed and waned in richness, with bony fishes finally coming to dominance. Reptiles entered the sea during the earliest Mesozoic and mammals early in the Cenozoic, but neither group became very rich in marine species.

Taxonomic Turnover

Relative clade richnesses vary considerably across Phanerozoic time. In **Figure 4**, the changing assemblages of dominant clades are classed into three major faunas. The Cambrian Fauna (labeled €), composed dominantly of trilobites (Arthropoda), does not diversify during the Ordovician and is overtaken by the expanding clades of the Paleozoic Fauna (labeled Pz), dominated by articulates (Brachiopoda) and crinoids (Echinodermata). The Paleozoic Fauna is decimated by the P/T extinction and does not increase significantly thereafter, and is overtaken by the diversifying Modern Fauna (labeled Md), which is dominated by mollusks and fishes. Elements of all of the faunas are present throughout the Phanerozoic.

Figure 5 depicts the great variety of family richness histories recorded for marine classes and phyla; the dominance of the characterizing clades during each of the three faunas is clearly evident. There are some general features that link the diversity patterns to evolutionary rates that seem to be inherent in the clades. The dominant clades of the Cambrian Fauna have very high evolutionary turnover rates—high rates of both diversification and extinction. The dominant clades of the Paleozoic Fauna have moderately high turnover rates, and those of the Modern Fauna have the lowest turnover rates of the dominant clades. As a result, the extinction rate for all families combined, excluding the major extinction events, declines steadily throughout the Phanerozoic. Evidently, a strategy of being resistant to extinction is superior to having a high speciation rate, perhaps because slight inclement environmental fluctuations can force a high-turnover lineage too close to extinction to recover. Note that the presently dominant bivalve and gastropod mollusks, slow-turnover clades, increase their relative representations inexorably throughout the Phanerozoic, and are not greatly affected even by the P/T extinction. A few clades that have fair preservation potentials can be shown to have survived for hundreds of million of years despite having very low diversities; the inarticulate brachiopods and the scaphopod mollusks are classic examples (see **Figure 5**). These are low-turnover clades; if they had high turnovers they would presumably have been swept away by even a small extinction event. Both speciation and extinction rates are probably tied to population parameters that of course evolved without respect to clade longevity or dominance,

which in a sense are merely side effects, though they profoundly influence the composition of the world's biotas.

Phanerozoic Terrestrial Biodiversity

Plant Diversity

"Land plants" include two major groupings: forms such as mosses and liverworts, collectively termed bryophytes, which lack a water-transporting system; and the tracheophytes, which possess vascular tissues that conduct water vertically and permit significant upward growth. It seems likely that tracheophytes arose from among the mosses, perhaps more than once. The earliest fossil record of plants on land may be furnished by spores of Middle Ordovician age that are possible bryophytes; tracheophytes probably date from Early Silurian, but their vegetative elements first appear in the Middle

Silurian. From then through the Devonian, a plexus of early plant types diversified, and from this plexus the modern groups of lycopods, horsetails, ferns, and gymnosperms evolved by latest Devonian time; there were forests before the close of the Devonian. This early burst of disparity is similar to that found among animals, but the richest of living plant groups, the angiosperms or flowering plants, appear much later, arising perhaps in the Late Jurassic but spreading during the Late Cretaceous and dominating Cenozoic plant associations. There is no animal analog for the late origination of a dominant major taxon, except for the class Mammalia, also terrestrial of course. However, the disparity indicated in the pollen record of angiosperms has been investigated, and it shows an early burst of disparity increase in the Early Cretaceous that gradually tapers off to a plateau by late in the Cretaceous. Evidently angiosperm "body" plans were evolved early in the history of the group and the rise of species richness followed later, the same pattern that is found within many

Figure 6 Phanerozoic diversity in the terrestrial fossil record, showing plant and animal family richness by phylum, class, or other higher taxon. Geologic periods are as in **Figure 3**. marine invertebrate groups and in numbers of vertebrate groups. **Figure 6** indicates the relative richness of major land plant groups through time as judged from their fossil records.

Animal Diversity

Invertebrates

Animals came ashore with the earliest plants, so far as can be told. It is quite possible that early terrestrial animals fed on bacteria, fungi, or protists and were ashore before tracheophytes; early arthropod burrows are reported in Ordovician soils. However, the earliest undisputed terrestrial animal remains, of arthropods, are from the Late Silurian. Because these fossils are predators (primitive centipedes and an arachnid), there must have been by that time an extensive fauna of primary consumers and a fairly complex ecosystem, evolved in

previous epochs. There is little evidence to judge how quickly and to what levels terrestrial invertebrate diversity rose during those times.

Insects evidently arose in the Early Devonian, and they have a relatively rich fossil record for a terrestrial group, being richer than the vertebrate record. The same species proportions found among living orders are also found among Tertiary fossils, suggesting that the insect record, while certainly incomplete, is not heavily biased taxonomically, and that at least their major fossil trends probably reflect actual paleobiological trends. During their earliest, Devonian history, insects are spottily represented; most of them are predators, whereas the primary consumers seem to have been chiefly detritus feeders; little herbivory is found. Insects underwent a significant expansion in the Carboniferous, and species richness rose to a high just before the major Permo-Triassic extinction, which affected insects significantly (see **Figure 6**).

However, the insects rebounded, rising steadily to their present overwhelming richness. Probably the rise was more evenly distributed in time than indicated in **Figure 6**, for there are some spectacularly rich insect faunal localities in the Late Tertiary, while equivalent faunas are not yet known from earlier deposits. As with marine invertebrates, significant morphological disparity was reached very early in insect history, preceding the greatest rises in richness. Though insect richness seems closely tied with the richness of the angiosperm flora, insect disparity, even including the evolution of the array of mouthparts and feeding structures present today, was largely accomplished well before the origin of angiosperms.

Chordates

All the primitive groups of jawed fishes are found in terrestrial aquatic deposits during the Middle Paleozoic, but on land as in the sea it was the bony fishes (Osteichthyes) that radiated to produce rich faunas that dominated in fresh waters, from the Devonian onward. The richness of terrestrial fossil fish faunas declined significantly in the Mesozoic, perhaps partly owing to a poor aquatic fossil record from that Era.

Tetrapods first appear in the Devonian, possibly Early Devonian, in effect as part of the general radiation of fishes, but with limbs that eventually permitted locomotion on land and led to the evolution of the Amphibia. The fossil record of this group is very sparse, but it is clear that the amphibians diversified extensively to reach a level of family richness comparable to today's by the close of Carboniferous time. The early amphibians were rather different from living forms, however, and included large animals, which were eventually replaced ecologically by reptiles. Three important groups arose from amphibian stocks, one leading to reptiles, one to mammals, and one to dinosaurs and birds. The early histories of these groups are so poorly known that their patterns of diversification cannot be accurately reconstructed. It is possible that both reptiles and dinosaurs gradually increased in richness and diversity through most of the Mesozoic era. The richness of these clades was reduced drastically during the extinction at the close of the Cretaceous.

While mammals must have diversified as well during the Mesozoic, it is in the early Cenozoic that their fossil record is marked by a burst of new appearances and, by about 10 million years after the start of the Cenozoic, all of the 17 modern orders of placental mammals had appeared. Only two of these orders are known from the Cretaceous, and while it is likely that most trace their roots to a few tens of millions of years earlier, mammals were clearly a minor though probably not unimportant part of the tetrapod fauna before the Cretaceous-Tertiary (K/T) extinction. It is usually assumed that mammals replaced dinosaurs, which became extinct at the K/T boundary, in ecological roles that permitted large body sizes. The only dinosaur descendants today are birds, which have a poor fossil record. Modern bird orders are unknown before the Cenozoic, suggesting that there was a significant K/T extinction of birds, leading to the radiation that produced modern types. There must indeed have been a significant diversification of birds during the Cenozoic, but as the roots of the modern lineages are uncertain and the bird record is poor, the pattern of bird diversity increase has not been established.

Principal Biodiversity Factors

Plate Tectonics and Global Heterogeneity

The geographic pattern of land and sea is constantly changing due to the processes of plate tectonics, which create and destroy the crust of the earth. At present the crust is divided into about 6 major and 14 minor crustal plates. New crust is added at one plate margin, a rift marked by deep-sea ridges, from sources of molten rock in the earth's interior. At the opposite plate margin, the crust plunges back into the interior, its descent marked by deep-sea trenches or "subduction zones"; this crust then remelts. Continents or islands on a crustal plate therefore move across the earth's surface, from the constructional margin toward the destructional margin, as if on a conveyor belt. Continents separated by a rift will diverge as they are carried apart on their respective plates, and continents will fragment if a rift cuts across them. On the other hand, continents separated by a subduction zone will converge, and if they meet they can weld together. The rates of movement of the plates are only several centimeters per year. Nonetheless, because plate tectonic processes have been incessant since well before the origins of animals and plants, the continents and oceans have changed their numbers, sizes, and geographic configurations over the many millions of years since those organisms first evolved.

As continents drift across the earth's surface they enter new climatic zones, and as oceans enlarge or shrink or change their shapes, the oceanic circulation changes, with warm or cool currents directed to different regions. The biota of any given area will evolve to adjust to the changing conditions, and may become enriched, perhaps if moving into the tropics, or depauperate, perhaps if moving into high latitudes. At the same time, migration routes are opened or closed by the shifting geography, permitting invasions of biotas into some regions while isolating the biotas of other regions. The biodiversity patterns both on land and in the sea reflect the environmental patterns created by plate tectonic processes.

In addition to its effects on rearranging regional biodiversity patterns, changes in global geography can significantly affect global biodiversity levels. The most impressive example is in the rise of biodiversity during the last 200 million years or so, from the Middle Mesozoic era through the Cenozoic era. At the beginning of the Mesozoic, the continents were welded together into a supercontinent, called Pangaea. Although Pangaea was certainly environmentally heterogeneous, with large climatic and topographic variations, the climatic zones tended to be occupied by widespread biotas that could spread across what are now separate continents. In the seas, the shelf encircled the single supercontinent in an essentially uninterrupted band. While the distribution of species was limited by climatic zonation and perhaps regional habitat peculiarities, even shallow-water species tended to be relatively widespread and of course were largely confined to the one shelf, though perhaps some were present on oceanic islands, of which little is known. As the Mesozoic passed, however, the continents were traversed by rifts and began to break up into smaller landmasses, between which were arms of the sea that finally widened into oceanic expanses. By the

close of Early Cenozoic time, all of the present continents that are now separated had broken from each other.

Species that could once range widely across Pangaea became isolated on separate continents. As the continents dispersed into different climatic zones and developed different topographies, their terrestrial biotas each evolved distinctively in response to local conditions and events. For example, North America, Eurasia, and Australia each developed distinctive temperate biotas, and the tropics of the Americas became distinct from the Old World tropics and those of the western Pacific. In the sea, the growing geographic differentiation was even more profound, as new shelves appeared on each side of the new oceans, significantly raising the number of isolated shelf segments. As on land, each continent evolved a distinctive biota in response to the unique set of environmental conditions and events that developed in each region. The heterogeneity of world environments thus increased greatly during this period, on a global scale. These plate tectonic effects are responsible for a significant part of the important rise in standing global marine diversities during the Mesozoic and Cenozoic as represented at the family level in [Figure 4](#); an accompanying rise occurred in the continental biota.

Climate Change

Climate is another major factor governing global biodiversity. For example, earth underwent a general cooling trend during the Cenozoic, although there were shorter warming and cooling events superimposed on the generally falling temperature curve. The temperature change was greatest in high latitudes, thus increasing the temperature differential between the poles and the equator. The margins of the tropics were shifted toward the equator, the tropics became compressed, and cooler climates came into existence in high latitudes, shifting equatorward themselves as cooling continued, to be replaced poleward by still cooler climatic regimes.

In the sea, the increasing temperature gradient made for a markedly increased provincialism. Tropical species whose biology was related to climate became progressively more restricted to lower latitudes, with some occasional, relatively short-lived reversals in which species tolerant of lower temperatures arose and diversified in the more poleward regions. Because the major rifting that produced the Cenozoic continental pattern was primarily in a north-south direction, most major continental shelves trend north-south in the Cenozoic, as they do today, and so there was a rise in species richness on each shelf as the latitudinal thermal gradient increased, multiplying the effect on global marine biodiversity by the number of isolated shelves. The Cenozoic global marine rise in family richness shown in [Figure 4](#) is compounded partly of the increase in the number of isolated shelves following continental rifting and partly of the increased provincialism on each shelf created by an increasing thermal gradient; together they have formed a powerful engine of global species enrichment.

In terrestrial environments, family richness also increased during those Cenozoic events, and for the same reasons. The continental expanses provided for a three-dimensional array of habitats (including high mountains and basins) unlike the

rather two-dimensional array along the narrow, shallow continental shelves, and therefore the biotic response has been correspondingly more complicated in terrestrial than in marine environments. Not only did high-latitude climate zones open up, but high-altitude regions became cooler, increasing the contrasts between mountain and lowland environments. A lowering of rainfall in some continental interiors produced semiarid plains and steppes. The biota responded to these increases in environmental heterogeneity by producing, for example, alpine and grassland plants and animals, thus enriching both the flora and fauna. The species richness of angiosperms among plants and of insects among animals profited the most from these events.

During the Late Cenozoic, as cooling has continued in high latitudes, massive ice accumulations on a subcontinental scale have produced a series of glacial ages interrupted by warmer interglacial periods, most pronounced during the Pleistocene, which began about 1.6 million years ago. Some regional extinctions occurred during the early onset of cold periods, but in general there has been little extinction, and thus no significant lowering of global biodiversity, associated with these climatic swings. Instead, the biotas of both land and sea have tended to migrate with their climatic zones, southward during glaciations and northward during interglacial times. Thus regional diversities have changed as species have migrated, but overall diversity has not been significantly affected. Indeed, the Recent biosphere may be the richest in species during the entire history of animals and plants, at least prior to the deleterious influences of human activities on biodiversity.

Extinction Events

Changing environments have often provided opportunities for the origin of species, some of which have clearly led to major morphological novelties and enhanced morphological disparity. At the same time, changing conditions have led to the extinction of species, which has occurred more or less continually over Phanerozoic time. As noted earlier, extinction rates vary among taxa, whose histories tend to reflect their rates of turnover. The species richness of a taxon results from an interaction between its rates of speciation and extinction. Thus when there has been some unusually profound disturbance to the global environment, and extinction rates have become unusually high, species richness has fallen dramatically in events called mass extinctions. The most drastic such event, recorded in marine fossils, was the Permian-Triassic (P/T) extinction about 250 million years ago, at the close of the Paleozoic era. As many as 90% of marine species may have become extinct across the P/T boundary (see [Figures 5](#) and [6](#)). This extinction was highly differential; the groups that did best in surviving the extinction and in rediversifying were those that dominate the marine fauna today. Disparity as well as richness was affected; some entire classes and orders of marine invertebrates disappeared. Brachiopods, crinoids, and other groups that were dominant before the extinction were reduced to minor roles. The causes of this extinction, and the extent of its effects on the terrestrial biota, are not yet clear.

There have been a number of other mass extinctions (five major events in all) and numerous regional extinctions that were severe locally. The most famous of the mass extinctions, the K/T, occurred about 65 million years ago at the close of the Mesozoic era, although it did not have as profound an effect on the marine environment as the P/T event. The K/T extinction strongly affected terrestrial as well as marine life. It probably resulted from the impact of an extraterrestrial object, such as a meteor, with the earth.

The "background" extinctions that account for the general turnover of taxa are accompanied by "background" speciations, so that species richness levels do not change much during normal turnover and tend to be significantly affected by background effects only during trends that last tens of millions of years or more. However, the more abrupt, severe regional and mass extinctions are not immediately compensated by correspondingly massive speciations, and indeed the recovery of species richness usually requires millions of years following a mass extinction. For phyla, classes, or orders that are lost to extinction, there is no recovery at all, and the unique gene regulatory systems involved in their architectures are gone forever.

Clearly, biodiversity data from the fossil record support the notion that species richness is largely associated with environmental heterogeneity, and thus the preservation of species diversity can be promoted by preserving habitat diversity. There are entire animal phyla that are represented today by

very few species: the phylum Phoronida by only 12 or so, and the phylum Priapulida by perhaps 17, for example. These phyla harbor uniquely organized genomes that have been present for over half a billion years of earth history, and that are largely unstudied. Their preservation should be a priority, for they represent major elements in the disparity of the present biosphere.

Glossary

Genotype The genetic constitution of an organism.

Heterozygosity The presence of alternate alleles at a given locus in a diploid organism (e.g., A_1A_2).

Homozygosity In a diploid organism, the presence of the same alleles at a given locus (e.g., A_1A_1).

Iteroparity Repeat breeding (see *semelparity*).

Semelparity Breeding once and dying; sometimes called “big bang” reproduction.

Introduction

Plants and animals show profound variation in all aspects of their life histories, which include age at maturity, age-specific fecundity, survival rate, size at birth, and so on. This variation is evident at both the inter- and intraspecific levels. For example, at the interspecific level, species of flatfish range in size from 2 cm-long tropical species that reproduce within their first year of life to behemoths such as the Pacific Halibut (*Hippoglossus hippoglossus*), which exceed 200 cm and take over 10 years to mature. Though the range in variation within a species is not as dramatic as between species, it is still impressive, as illustrated by variation in the flatfish, *Hippoglossoides hippoglossoides*. In this species maturation occurs at age 3 years at a length of 20 cm in populations off the coast of Scotland while the same species requires 15 years to reach maturity at a length of 40 cm on the Grand Banks of Newfoundland. Longevity and maximum size are equally different in the two populations, Scottish fish reaching a maximum length of 25 cm and an age of 6 years, compared to 60 cm and 20+ years on the Grand Banks. Similar observations on variation in life history characteristics could be made in most taxa. But though the diversity of life histories is readily apparent, attempts to understand its origin and maintenance are still in their infancy.

Because fitness varies quantitatively among different life histories, a necessary tool for analysis is mathematical modeling. An influential factor encouraging the use of mathematical investigation into life history variation was Lamont Cole's 1954 paper, “The Population Consequences of Life History Phenomena,” which set out the basic mathematical framework by which the consequences of variation in life history traits can be analyzed. Cole's paper ushered in an era of research predicated on the integration of mathematics and biology in the study of the evolution of life history patterns.

In his review, Cole analyzed how changes in demographic attributes, such as the age at first reproduction, influenced the rate of increase of a population. Cole's paper gained widespread notice because of an apparent paradox with respect to the value of semelparity versus iteroparity:

For an annual species, the absolute gain in intrinsic population growth which could be achieved by changing to the perennial

reproductive habit would be exactly equivalent to adding one individual to the average litter size (Cole, 1954, p118, Cole's italics).

Thus, an annual species with a clutch size of 101 would increase in numbers as fast as a perennial that produces 100 young every year forever. There is obviously something amiss with this result, for perennials are common. While there is good evidence that survival and reproduction are negatively correlated it seems highly unlikely that perennial species are committing so much energy into reproduction that they cannot produce one more offspring. Cole's paradox derives from a failure to consider the consequences of juvenile and adult survival rates; specifically Cole implicitly assumed that the survival rate of juveniles is the same as that of the adults. In general, juvenile survival is lower (often by a great amount) than that of the adults and this means that the reproductive output of the annual must be greater than one for the annual to have the same gain in rate of increase as a perennial, the precise amount depending on the mathematical details of the model. Cole's paradox illustrates the need to formulate an analysis of life history variation within a mathematical framework where the biological assumptions are explicitly stated. Since Lamont Cole, the theoretical and experimental analysis of life history evolution has made enormous strides using two different analytical perspectives.

Two Frameworks for Analysis

The evolution of life history variation has been approached via two different modes of analysis, here termed phenotypic models and genetic models.

Phenotypic Models

In this approach no attempt is made to model the genetic basis of traits: it is simply assumed that there exists sufficient genetic variation that evolution is not constrained by genetic architecture. Is this a reasonable assumption? Most life history traits—such as age at first reproduction, fecundity, and survival—are not determined by simple Mendelian mechanisms such as single locus, two allele systems. More generally they

show continuous variation, or if dichotomous can be best interpreted under a threshold model in which there is an underlying continuously varying trait. Nevertheless, polygenic determination is not essentially different from the simpler case of a single locus with two alleles. In the one locus case the phenotype is determined by the additive action of the alleles, or one allele may show dominance. When one allele is dominant, the effect on the phenotype can be statistically decomposed into additive and dominance components. With two or more loci controlling a trait there may be interaction between loci. These interactions, termed epistasis, can produce a wide range of responses but are generally assumed to be absent (because most variation can be subsumed under the additive or dominance portion of genetic variance, this assumption is not as unreasonable as it might appear).

The average similarity between parent and offspring can be measured by the linear regression of mean offspring value (Y) on midparent value (X),

$$Y = (1 - h^2)m + h^2X \quad (1)$$

where m is the population mean of the parents and the slope of the regression, h^2 , is termed heritability in the narrow sense. More generally, heritability is defined as follows:

$$h^2 = \frac{V_A}{V_P} = \frac{\text{Additive genetic variance}}{\text{Total phenotypic variance}} \quad (2)$$

Heritability in the narrow sense, or generally simply heritability, must not be confused with heritability in the broad sense, V_G/V_P , which is a measure of the overall variance in the trait attributable to all genetic influences. Obviously h^2 varies between 0 and 1: at 0 there is no resemblance between parent and offspring due to the additive effects of genes, while at 1 the mean offspring value equals the midparent value. The importance of heritability for evolutionary theory is obvious: the higher the value of h^2 , the faster genetic changes in the population can occur. Most important from the point of view of life history theory, if heritability is zero for a particular trait or traits under consideration, then the optimal combination cannot be attained because the effects of selection on parents are not manifested in the offspring. Heritability estimates for different types of traits are shown in Table 1. While heritabilities for life history traits are typically lower than those less directly related (in general) to fitness, there is nevertheless sufficient genetic variation to permit rapid evolutionary change even under modest selection pressure.

While the assumption of sufficient additive genetic variation is reasonable with respect to the equilibrium conditions, the genetic architecture can considerably influence evolutionary trajectories and hence the phenotypic approach is contingent on the state having attained an equilibrium. The

method seeks to construct the fitness surface and hence the optimal combination of trait values.

Optimality Modeling

The concept of tradeoffs is central to present theories of the evolution of life history traits, for tradeoffs limit the scope of variation. Within the set of possible combinations there will be at least one combination that exceeds all others in fitness. Optimality analysis assumes that natural selection will drive the organism to that particular set. To initiate an analysis using the principle of optimality, we must designate some parameter to be optimized. In the present case we assume that there is some measure of fitness that is maximized by natural selection. The second step is to construct a set of rules that define the life history pattern of the organism, hypothetical or real, under study. Within these rules there will exist a variety of possible life histories; the optimal life history is that which maximizes fitness.

What do we do if the predicted life history does not correspond to that which is observed? The first point to note is that the principle of optimality is not under test. Failure to get a correct prediction is not taken as evidence that fitness is not being maximized, but it is taken to imply that the model is deficient. Having found that the initial model does not work we inquire into the assumptions of the model, namely the rules that define the range and scope of life history variation. These rules are changed either arbitrarily or based on further observation until agreement is gained between prediction and observation. Having found congruence, we are not able to say that therefore the component relationships are correct. The underlying components must be independently verified; a model is only the logical outcome of a set of interactions and the onus is on the person specifying those rules to demonstrate that they are indeed valid. Note again, that the assumption that fitness is being maximized is not under test, except to the extent that the particular measure chosen may be inappropriate. This does not mean that we assume that all traits and trait combinations are the result of adaptive evolution. But we do choose those that we have a priori reason to suppose are under selection.

A primary purpose of optimality modeling is to organize a program of experimentation and data collection. An adequate fit of a model to data gives us reassurance that a sufficient number of factors have been taken into account. Nevertheless, the validity of a model is continually under question and is challenged by the addition of more information. The more tests the model survives the greater the assurance that it is realistically capturing the important elements that determine the set of traits being studied.

Game Theory

Game theory is really a subset of optimality modeling: it is appropriate when interactions are frequency dependent. The approach comprises two essential elements. First, it is assumed that particular patterns of behavior will persist in a population provided no mutant adopting an alternate behavior can invade. Such stable combinations are termed evolutionarily stable strategies (ESS). The concept of the ESS is not unique to game theory: the maximization of fitness measures in

Table 1 A summary of heritability estimates for nondomestic animals

Comparison	Life history	Behavior	Physiology	Morphology
<i>Drosophila</i>	0.12	0.18	ns	0.32
All animals	0.26	0.30	0.33	0.46
Medians	0.26	0.37	0.31	0.51

optimality models are all ESSs within the context in which they are appropriate. Second, for each type there must be an assigned gain or loss in fitness when this type interacts with another individual. From this payoff matrix we compute the expected payoff for each behavior. For two behaviors to be evolutionarily stable, their fitnesses must be equal.

Genetic Models

Genetic modeling proceeds by first defining the genetic mechanism determining the phenotypic trait and then cranks the model through the appropriate mathematical machinery to obtain the equilibrium trait values. The critical problems are the correct definition of the genetic architecture and the estimation of the selection gradients.

Simple Mendelian Models

Consider a trait whose expression is governed by a single locus with two alleles, A_1 , A_2 . A selection coefficient (= fitness) representing their relative contribution to the next generation can be assigned for each of the three genotypes (Table 2). The change in the frequency of A_1 , p , is then easily obtained as

$$\Delta p = \frac{pq[p(w_{11} - w_{12}) + q(w_{12} - w_{22})]}{\bar{w}} \quad (3)$$

At equilibrium $\Delta p = 0$, and hence it is a trivial matter to predict the frequencies of the three genotypes at equilibrium and hence the mean trait value. Complexity can be added by making the fitnesses a function of density or frequency, but this does not change the basic mathematical approach.

Most traits of ecological interest, fecundity, age at maturity, clutch size, egg size, and so on are continuous in character. Even traits that appear dichotomous, such as liability to disease, wing dimorphism, diapause, and sex ratio, are best understood as being the result of some underlying continuously varying factor exceeding or not attaining a threshold for the expression of the trait. The expression of traits that show continuous variation are not, in general, the result of a single gene, nor two genes, but a large number of genes that acting additively produce a continuous spectrum of phenotypes. The analysis of such traits is the domain of quantitative genetics. This is largely a statistical approach to genetic variation and is founded on a mathematical analysis of variation rather than an understanding of how groups of genes interact to determine a particular trait.

Quantitative Genetic Models

The concept of heritability has already been introduced. For nonzero heritabilities, the rate at which the appropriate combination of trait values can be realized depends in part on

the value of the heritability and the intensity of selection, measured as the selection differential, S , the difference between the mean of the population and the mean of the selected parents. For a single trait it can be shown from Equation 1 that the response to selection (the difference between the mean population values in parental and offspring generations), R , is equal to h^2S . Since selection changes the gene frequencies, heritability must change at each generation of selection. This problem is avoided in the application of quantitative genetic theory to natural populations by assuming that selection is weak and population size large, thereby permitting mutation to replace variation eroded by selection. Whether this assumption is reasonable can only be answered empirically and at present there are insufficient data to draw any meaningful conclusion.

Traits are typically not inherited as separate independent units; rather, phenotypic values of several traits are typically controlled in part by a common set of genes. Thus selection on one trait will produce a change not only in the selected trait but also traits that are genetically correlated by virtue of shared genes (genetic correlations can also arise through linkage disequilibrium, but these are transitory and are ignored here). Selection on two traits, X and Y , will produce standardized (in phenotypic standard deviation units) responses R_X and R_Y

$$\begin{aligned} R_X &= \beta_X h_X^2 + \beta_Y h_X h_Y r_A \\ R_Y &= \beta_Y h_Y^2 + \beta_X h_X h_Y r_A \end{aligned} \quad (4)$$

where r_A is the genetic correlation between the two traits and β_X , β_Y are the standardized selection differentials on X and Y , respectively. The preceding equation can be more conveniently written in matrix notation, for which the typical notation is $\Delta \bar{z} = G\beta$, where $\bar{z}$ is a vector of trait means, G is the genetic variance-covariance matrix, and β is a vector of (unstandardized) selection gradients for each character.

The evolutionary trajectories for two traits can be easily visualized by constructing a plot of isoclines of equal fitness (defined by the selection gradients) and plotting the changes in trait means each generation as illustrated in Figure 1. If there is no genetic correlation between the two traits, the population will move rapidly to its optimal combination. For genetic correlations lying between -1 and $+1$, the trajectory is "warped" and if the genetic correlation is exactly ± 1 , the optimal combination may be unattainable (Figure 1). The reason for this can be understood by considering the regression of the additive genetic values of trait Y on X . According to the quantitative genetic model, we have $Y = c + bX + \text{error}$, where c and b are constants and the error term is normally distributed with mean zero. Provided the variance in the error term is not zero, any combination of Y and X is possible; hence, evolution can always move the traits to such a combination. However, if the variance of the error term is zero, which occurs when the (genetic) correlation between Y and X is ± 1 , then the traits are constrained to lie on the regression line. The number of cases in which r_A is exactly equal to unity is very small (see The Evolution of Life Histories). With more than two traits evolution can be constrained if one or several eigenvectors of the genetic variance-covariance matrix are zero (singular matrix).

Table 2 The derivation of the optimal trait value in a simple single-locus model

	A_1A_1	A_1A_2	A_2A_2	Sum
Ratios before selection	p^2	$2pq$	q^2	1
Fitness	w_{11}	w_{12}	w_{22}	
Ratios after selection	$p^2 w_{11}$	$2pqw_{12}$	$q^2 w_{22}$	$\bar{w}$

Figure 1 Hypothetical evolutionary trajectories for two traits. The solid lines define contours of equal fitness. Each dot represents the trait combination achieved after some specified number of generations. The values beside each trajectory indicate the genetic correlation between the two traits.

It is possible for there to be no response to selection in spite of both genetic variance for the trait and a phenotypic correlation with another trait under selection. The second observation is particularly important since it implies that a trait may be under selection but show no response. This can be most easily seen by relating the selection differential as a function of the selection gradient and phenotypic variance (V_{PX}) and covariance (Cov_P)

$$S_X = \beta_X V_{PX} + \beta_Y Cov_P \quad (5)$$

with a similar term for S_Y . Now suppose that (a) there is no additive genetic variance for trait Y , (b) trait Y is phenotypically correlated with X but genetically uncorrelated ($Cov_A = 0$), and (c) there is no direct selection on trait X (i.e., $\beta_X = 0$) but there is selection on trait Y (i.e., $\beta_Y > 0$). From Equation 5 it can be seen that a positive selection differential is generated ($S_X > 0$), but from equation 4 ($R_X = V_{AX}\beta_X + Cov_A/\beta_Y$) it is apparent that there will be no response to this selection, even if there is additive genetic variance for X . A likely case in which this situation can arise is when trait X is a heritable trait such as fecundity and Y is a trait such as nutritional status that might have zero heritability: thus well-nourished individuals have high fecundity, which gives them an apparent selective advantage, but this is not realized because selection is acting only on the environmentally determined component of fecundity. The mechanism described earlier, or ones conceptually similar, have been proposed for the observation of directional selection without evolutionary response in breeding date in birds, clutch size in birds, and tarsus length in birds.

The theory described here assumes that the genetic covariance (i.e., the genetic correlation) remains constant. As with heritability, selection changes allelic frequencies and hence must in principle change the genetic correlations, or more generally the genetic variance-covariance matrix. The G matrix will remain constant provided selection is weak and

population size large so that mutation can replace variance lost due to selection and drift.

Tradeoffs: A Central Feature of Life History Analysis

Tradeoffs are essential elements of all the above approaches. In the “phenotypic approach” it is implicitly assumed that the tradeoffs are genetically determined, otherwise there could be no evolutionary response. In quantitative genetic terms, this is interpreted as a negative genetic correlation between two traits. Thus it has been supposed that to demonstrate an evolutionarily important tradeoff it is sufficient to demonstrate that the tradeoff is expressed not only as a phenotypic correlation but also as a negative genetic correlation. However, as discussed earlier, a negative genetic correlation is not, in principle, a barrier to movement anywhere in parameter space. Thus while it is necessary for a tradeoff to be expressed as a genetic correlation for it to be evolutionarily significant, this is not a sufficient demonstration that the optimal combination will be governed by the tradeoff.

Empirical investigations of tradeoffs can be placed into three categories: (a) phenotypic relationships based on field or laboratory observations of unmanipulated situations, (b) experiments in which organisms were manipulated to vary the value of one trait (e.g., manipulation of clutch size to investigate subsequent survival of adults or young), and (c) demonstration of a negative genetic correlation between two traits, obtained by sib analysis or selection. Only the last measure provides definitive proof that the tradeoff is evolutionarily significant but there is, however, merit in the second approach because it can establish the mechanism generating the tradeoff. The first approach is suspect because of the covariation of traits that could produce false conclusions if such covariation is not taken into account. For example, reproduction may be determined by condition, those in poor condition not breeding; consequently it would not be surprising to find the survival rate of nonbreeders to be less than breeders.

There is no reason to suppose that all tradeoffs between life history traits will be negative, but we should expect a significant proportion to be so. In fact, the distribution of genetic correlations between life history traits is very broad (Figure 2), with 39% being negative but few estimated to be -1 . In contrast, only 23% of genetic correlations between morphological traits are negative. Thus there do appear to be tradeoffs that will at least impede the evolution of life history traits.

The Evolution of Life Histories

The starting point of many analyses of evolutionary change, most particularly that of optimality modeling, is the assumption that there exists some variable maximized by selection. The issue of what is being maximized has been the subject of much discussion, partly because the appropriate measure of fitness changes with circumstance and method of analysis. Broadly, measures of fitness can be separated into two groups: global measures and local measures. A global measure of fitness is one that involves the interaction of all life

Figure 2 Distributions of the genetic correlation between Morphological traits ($M \times M$) and Life History traits $L \times L$.

history components, the best example being Fisher's Malthusian parameter r . Local measures assume that maximization of a fitness component will also maximize the overall fitness of the organism: for example, a common local measure used in foraging theory is the net rate of energy intake. This is an appropriate measure if it can be shown that maximizing this rate does not detrimentally affect other components of fitness, in which case maximizing net rate of energy intake will also increase global fitness.

Local measures are generally tailored for the particular analysis under consideration, but there now exists a general consensus, and more important sound theoretical rationale, of what global measures are likely maximized by natural selection.

Static Environments

A population growing in an unlimited, homogeneous, and constant environment follows the simple exponential growth function

$$\begin{aligned} \frac{dN(t)}{dt} &= rN(t) \\ N(t) &= N(0)e^{rt} \end{aligned} \quad (6)$$

where $N(t)$ is population size at time t and r is the intrinsic rate of increase, comprising the difference between instantaneous rates of birth and death. Equation 6 can also be written as

$$N(t) = N(0)(e^r)^t = N(0)\lambda^t \quad (7)$$

The symbol λ is called the finite rate of increase and is sometimes used instead of r .

Suppose there are two clones with population sizes, $N_1(t)$ and $N_2(t)$, respectively, the first with an intrinsic rate of increase of r_1 and the second with r_2 , with $r_1 > r_2$. The ratio of population sizes after some time t , given that both clones start with the same population size is,

$$\frac{N_1(t)}{N_2(t)} = e^{(r_1 - r_2)t} \quad (8)$$

It is clear that as time progresses this ratio will increase, clone 1 becoming numerically more and more dominant in the

combined population. This conclusion does not depend on the two clones beginning with the same population size: differences in starting condition simply accelerate or retard the rate at which clone 1 increases in frequency relative to clone 2.

For these two clones, an appropriate measure of fitness is r , since the frequency of the clone with the highest value of r will increase toward unity. Thus any mutation in a set of clones that increases r by changing rates of birth or death will increase in frequency in the population. There are no difficulties in assigning r as a measure of fitness in the preceding circumstances. Difficulties arise, however, when sexual reproduction and age structure are introduced. Suppose we have a random mating population in which a mutation arises that increases birthrate or decreases death rate. Since the mutant will initially be rare in the population, its fate can be ascertained by considering the birthrates and death rates of the heterozygote alone. If the heterozygote's rate of increase is enhanced, the mutation will increase in frequency in the population, but its ultimate fate depends on the relative birthrates and death rates of the homozygotes and heterozygotes bearing the mutant allele. If the homozygote carrying both mutant alleles has a higher birthrate or a lower death rate than the heterozygote, the mutant allele will eventually be fixed in the population; otherwise the population will reach a stable polymorphism.

The general assumption, stemming from the work of Fisher, has been that r can be associated with genotypes that follow particular life histories and that selection will favor that genotype with the highest value of r . In an age-structured population, the rate of increase is obtained by solving the characteristic equation

$$\int_0^\infty e^{-rx} l(x) m(x) dx = 1 \quad (9)$$

where $l(x)$ is the probability of surviving to age x and $m(x)$ is the number of female births at age x . The discrete time equivalent of this is

$$\sum_{x=1}^{\infty} e^{-rx} l(x) m(x) = 1 \quad (10)$$

Note that in the discrete version the initial age is subscripted as 1 not 0. The important issue to be considered is the fate of a mutant that increases r . Charlesworth demonstrated that to a rough approximation the rate of progress of a rare gene eventually becomes directly proportional to its heterozygous effect on r . In this case, the probability of survival of a mutant gene of small effect in a near-stationary population is largely determined by its effect on r . Following a more detailed analysis, Charlesworth (1994) concluded

that for the case of weak selection and random mating with respect to age, the intrinsic rate of increase of a genotype or, more generally, the mean of the male and female intrinsic rates, provides an adequate measure of fitness in a density-independent and constant environment.

Lande tackled the problem of applying quantitative genetic theory to the evolution of r in a population. Assuming weak selection, large population size, and a constant genetic

variance-covariance matrix, Lande showed that in a constant selection regime, life history evolution continually increases the intrinsic rate of increase of a population until an equilibrium is reached. The intuitive appeal of r as a suitable measure of fitness thus receives qualified support from both population genetic and quantitative genetic theory.

If the population is stationary, r is zero and the characteristic equation reduces to

$$R_0 = \int_0^\infty l(x)m(x)dx = 1 \quad (11)$$

R_0 is termed the net reproductive rate and is the expected number of female offspring produced by a female over her life span. The use of R_0 makes analysis easier and can be justified if r is very close to zero or if the density-dependent or other factors that maintain the population at some relatively stable value do not impinge on the traits under consideration. For example, population size might be controlled by density-dependent mortality in the larval stage, while the object of study is the evolution of female age at maturity. In this case we can examine the relationship between the age at maturity and fitness under the working assumption that genotypes do not differ in the characteristics of their larvae. Since population size is stable, the expected lifetime fecundity, R_0 , is then the appropriate measure of fitness.

In some analyses, fitness is determined from the reproductive value at age x , $V(x)$,

$$V(x) = \frac{e^{rx}}{l(x)} \int_x^\infty e^{-\eta y} l(y) m(y) dy \quad (12)$$

The reproductive value of an individual of age x is a measure of the extent to which it contributes to the ancestry of future generations. Williams (1966) postulated that natural selection maximizes r by maximizing reproductive value at every age. A mathematically correct statement of the principle is "reproductive value at each age is maximized relative to reproductive effort at that age, although not necessarily with respect to effort at other ages."

The preceding approach has been very successful in accounting for variation in life history traits. An illustration of this is the analysis of the optimal size at first reproduction in *Drosophila melanogaster*. In *D. melanogaster* body size increases with development time and fecundity increases allometrically with adult body size, which is fixed on eclosion from the pupa. The age schedule of female births is triangular in shape (Figure 3) and is described by the equation

$$m(x) = \frac{1}{2} c_1 L^{c_2} (1 - e^{-c_3(x-c_4)}) e^{-c_5 x} \quad (13)$$

where the c_i s are constants, L is thorax length, and x is age. Thorax length, L , scales the age schedule of reproduction, larger females producing more eggs, but does not change its position. The constant c_1 is the product of two constants: the coefficient of proportionality within the allometric relationship between length and fecundity, and the proportion of eggs that fail to hatch.

Development time, $d(L)$, scales to body size according to the relationship (Figure 3)

$$d(L) = c_6 L^{c_7} + c_8 \quad (14)$$

Figure 3 Relationship between body size and life history traits in *Drosophila melanogaster*. Upper panel: Age schedule of reproduction for small (solid line) and large (dashed line) females. Lower panel: Development time and survival from egg to adult in relation to adult thorax length.

Thus development time scales allometrically with size except for the constant c_8 , which represents time required for the eggs to hatch and the development within the pupa, both of these components being independent of size.

Because information on mortality rates are so poorly known, it was assumed that instantaneous rates remain constant in the adult and larval phases at M_a and M_l , respectively. Probability of surviving the larval period, $l(L)$, is thus (Figure 3)

$$l(L) = e^{-M_l d(L)} \quad (15)$$

Drosophila melanogaster is a colonizing species and hence the appropriate measure of fitness is r . Combining the previous relationships, we obtain the characteristic equation

$$\sum_{x=1}^{\infty} \frac{1}{2} e^{-r[x+d(L)+c_4]-M_l d(L)-M_a(x+c_4)-c_5 c_4 c_1 L^{c_2}} (1 - e^{-c_3 x}) e^{-c_5 x} = 1 \quad (16)$$

where, for convenience age has been rescaled to begin at the first day of egg laying. Though this equation is tediously long, its solution presents no great difficulty. Briefly, the method is, first, to evaluate the series making use of the fact that it is a geometric progression and, second, to differentiate implicitly to obtain the optimal length at maturity. The optimum thorax length depends on adult mortality, larval mortality, and the constant initial "mortality" component (p or c_1). Figure 4 shows the relationship between r and thorax length using values obtained from laboratory stocks and estimates from wild populations. The predicted maximum, 0.95 mm, falls

Figure 4 Estimated relationship between fitness, as measured by the rate of increase, and thorax length in *Drosophila melanogaster*.

very nicely within the observed range in thorax length of 0.90 to 1.15 mm.

Stochastic Environments

Environments are typically variable in both time and space. While the assumption of a constant environment may be a reasonable first approximation in many cases, there will be many others in which variation cannot be ignored. The simplest case to consider is where the environment is stochastic and there is no cue as to future conditions.

In a stochastically, temporally fluctuating environment, the correct measure of fitness is the geometric mean of the finite rate of increase. The rationale for this measure is as follows: the size of a population after t time intervals is given by

$$N(t) = N(0)\lambda_1\lambda_2\ldots\lambda_t = N(0)\prod_{i=1}^t \lambda_i \quad (17)$$

The arithmetic and geometric means are

$$\begin{aligned} \text{Arithmetic mean} &= \frac{1}{t} \sum_{i=1}^t \lambda_i \\ \text{Geometric mean} &= \sqrt[t]{\prod_{i=1}^t \lambda_i} \end{aligned} \quad (18)$$

It is obvious that the geometric mean describes the long-term average per generation change in population size and hence is the parameter that reflects the fitness of different strategies. If r is used in place of the finite rate of increase, the appropriate measure of fitness is the arithmetic mean of r . This can be demonstrated as follows: dividing time intervals into small units we can write

$$N(t) = N(0)e^{r_1}e^{r_2}\ldots e^{r_t} = N(0)e^{\sum_{i=1}^t r_i} \quad (19)$$

from which it is readily apparent that the correct measure of fitness is the arithmetic average of r .

Figure 5 Reaction norms between two life history traits (larval mortality, development time) and temperature in *Drosophila melanogaster*.

Consider two genotypes living in an environment that comprises two types of year, “good” and “bad,” each occurring with equal frequency. In “good” years, genotype A has a finite rate of increase of 2 and in a “bad” year a finite rate of increase of 0.5, while genotype B has finite rates of increase of 1 and 1.1, respectively. The arithmetic averages of A and B are 1.25 and 1.05, respectively, but the geometric averages are 1 and 1.1. Thus genotype B has the highest long-term fitness although it has a smaller arithmetic finite rate of increase. Genotype A increases more than genotype B in “good” years but suffers a greater reduction in “bad” years. The relatively high fitness of genotype B resides in the fact that although it has a smaller arithmetic average, it also has a smaller variance in its finite rate of increase. In a stochastic environment the highest fitness may be gained not by the production of a single phenotype but by a genotype producing a range of phenotypes. Such bet-hedging strategies are common, an example being the production of both diapausing and direct-developing offspring in both invertebrates and plants.

Predictable Environments

Most environments show predictable changes either as a result of biotic factors (e.g., overgrazing, community succession) or abiotic factors (e.g., winter, monsoons). Suppose factors that affect one or more life history characters are fully predictable—that is, given some cue E the life history characters will be changed from their present values to values that can be related to E by some function. For each case there is some optimal combination of trait values: given the predictable nature of the cue means that the organism’s life history can be altered to accommodate the new conditions. Suppose, for example, that when the environmental conditions are E_i the optimal clutch size is C_i . Upon receipt of the environmental cue, the organism produces the optimal clutch size, C_i . This relationship between trait value and environment is called a norm of reaction, whether or not it is optimal. Reaction norms are ubiquitous. Two examples of reaction norms are shown in **Figure 5**. A reaction norm may be adaptive or a nonadaptive (even maladaptive) physiological response to the environment. To demonstrate that a reaction norm is adaptive requires that we use the set of tradeoff functions related to the environment to predict the optimal

reaction norm. Consider, for example, the question asked by Stearns and Koella (1986, p. 894): "How should an organism encountering an unavoidable stress that results in slower growth alter its age at maturity to keep fitness as high as possible despite the constraints imposed by slower growth?"

To address this question, Stearns and Koella used the following hypothetical model

1. Fecundity increases with body size, which increases with age:

$$W(x) = c_1(1 - c_2e^{-kx})$$

$$m(x) = c_3W(x) + c_4 \quad (20)$$

where $W(x)$ is size at age x , k is the parameter determining the rate at which the asymptotic size is approached, and c_1 – c_4 are constants.

2. Adult mortality rate, M_a , decreases with growth rate according to the function:

$$M_a = \frac{C_5}{k^{C_6}} \quad (21)$$

3. Mortality rate of juveniles, M_j , is a function of the component of adult mortality, c_5 , plus an amount that decreases with age at maturity, α , and growth rate, k :

$$M_j = c_5 + \frac{c_7}{\alpha^{C_8} k^{C_9}} \quad (22)$$

Stearns and Koella assumed that fitness is maximized by maximizing r . The predicted norms of reaction between age and size at maturity for four possible scenarios are illustrated in **Figure 6**:

1. Mortality rate and growth rate independent ($c_6 = 0$, $c_9 = 0$). Decreases in growth rate, k , favors an increase in the age at maturity and a decrease in the size at maturity.
2. Juvenile mortality rate increases as growth rate increases ($c_6 = 0$, $c_9 > 0$). As with the previous case, decreases in k favor an increase in the age at maturity and a decrease in the size at maturity. The actual norm of reaction may have the same shape as case 1 or be sigmoidal.
3. Adult mortality rate increases as growth rate decreases ($c_6 > 0$, $c_9 = 0$). The optimum norm of reaction has the same shape as case 1 but is reversed, size at maturity and age at maturity being positively related.
4. The adult and juvenile rates are variable ($c_6 > 0$, $c_9 > 0$). The relationship between age and size at maturity is "keel-shaped." The portion of the curve in which size at maturity is an increasing function of age at maturity only occurs when adult mortality rates exceed juvenile mortality rates by a factor of 100 or more. Thus, generally the trajectory is determined by mortality rates of juveniles.

The message from the preceding analysis is that reaction norms can be quite complex and dependent not only on the

Figure 6 Predicted norms of reaction between size and age at maturity for the life history model described in the text.

functional relationships determining the tradeoffs but also the parameter values. The situation is made even more complex if the environment is spatially variable: in this case the appropriate fitness measure is the overall r , not the r that is characteristic of a particular environment. This requires modifying the characteristic equation to

$$\int p(h) \int l(x, h) m(x, h) e^{-rx} dx dh = 1 \quad (23)$$

where $p(h)$ is the probability of habitat h occurring. The optimal combination of trait values can be markedly different from the average set determined by considering each habitat separately.

For reaction norms to evolve to produce the optimal response, there must be genetic variation in how individuals respond to the environment (i.e., there must be genetic variation for phenotypic plasticity). The evolution of phenotypic plasticity can be addressed using two apparently different mathematical perspectives: the character state approach and the reaction norm approach. Both approaches are actually interchangeable and each has advantages and disadvantages.

The character state approach is based on the assumption that the same trait measured in two environments can be considered as two traits that are genetically correlated. This is illustrated in **Figure 7**, where each line represents a separate genotype. If the lines joining the phenotypic values in the two environments (E_1 and E_2) intersect at a common point between E_1 and E_2 , the genetic correlation between the two traits is -1 (**Figure 7**, panel D). If the lines intersect outside the range E_1 to E_2 , the genetic correlation is $+1$ (**Figure 7**, panel A; note that parallel lines also produce a genetic correlation of $+1$, since mathematically their point of intersection is at the

Figure 7 Phenotypic plasticity in two environments as viewed from the character state perspective. The panels on the left show the character states in the two environments E_1 and E_2 , each line joining the trait values of a single genotype (the reaction norms of the genotype). The panels on the right show the regression of the trait value from the second environment, $X(E_2)$, on the trait value from the first environment, $X(E_1)$. A: The reaction norms meet at a single point beyond the range of the two environments. The correlation between trait values is $+1$. Note that parallel reaction norms also give a genetic correlation of $+1$ (mathematically this is because the lines meet at infinity). B and C: The reaction norms cross at several points within the range of the two environments. Depending on the distribution of intersections the genetic correlation will be positive but less than $+1$ (B), zero (C), or negative but greater than -1 (not shown). D: The norms of reaction intersect at a single point between the two environments. In this case the genetic correlation is -1 . The triangles show a hypothetical optimal combination of trait values. Because in cases A and D all the points lie on a single line ($r = \pm 1$), this combination may not be achievable. In all other cases, because in principle the distribution about the regression line is normal (i.e., no value is excluded), selection can move the population to the joint optimum.

point of infinity point beyond E_1 or E_2). The genetic correlation will differ from ± 1 if there is no common point of intersection (Figure 8, panels B and C).

While the character state approach sees the phenotype as two points in state space, the norm of reaction approach sees a

Figure 8 A pictorial representation of the two viewpoints of phenotypic plasticity. The character state approach (upper panel) focuses attention on the trait values in the two environments, while the reaction norm approach (bottom panel) focuses on the line joining the trait values.

line (Figure 8). Thus, for two environments phenotypic variation can be described as $X(E) = c_0 + c_1E + e$, where the two parameters c_0 and c_1 are viewed as traits, and e is an error term that is normally distributed with mean 0. Evolutionary change in X depends on the heritabilities of c_0 and c_1 and the genetic correlation between them. If the genetic correlation is ± 1 then the line that is genetically fixed and corresponds, as it should, to the cases A and D in Figure 7. This description is merely an alternate formulation of the character state approach. The conceptual advantage of this approach is that it extends quite naturally to continuously distributed environmental variables such as temperature. The preceding model can clearly apply to any linear reaction norm; if the relationship between trait and environment is more complex, a more complex function can readily be substituted, for example, the quadratic $X(E) = c_0 + c_1E + c_2E^2 + e$.

The evolution to the optimal reaction norm could be constrained. Suppose, for example, the reaction norm were linear but the optimal reaction norm were quadratic: in this case the optimal reaction norm cannot be attained. If some arbitrarily complex polynomial function is assumed, then many shapes are possible and no constraint will ensue. While there are abundant data indicating that genetic variation for phenotypic plasticity of life history traits is common, there are few data suggesting that the evolution of reaction norms are constrained.

The study by Weis and Gorman (1990) on the evolution of gall size in the insect *Eurosta solidaginis* is one of the few studies that has examined selection on a reaction norm in a natural population. *Eurosta solidaginis* attacks the goldenrod *Solidago altissima*, laying its eggs in the stems and the larvae causing the formation of a gall. From field data, Weis and Gorman determined that survival was a complex function of gall diameter, with an optimum at approximately 24 mm (Figure 9). On the basis of analysis of 16 full-sib families, they obtained a linear relationship between final gall diameter and the time lag between oviposition and gall initiation (Figure 9). Because the time lag showed variation associated with plant sibship but not among insect sibship, Weis and Gorman argued that time lag is a trait of the plants and not the insects. Thus time lag is, from the insect's perspective, an environmental gradient associated with the plant. The heritability of the gall-size/lag time intercept was determined as 0.21 (SE = 0.18) and the slope as 0.54 (SE = 0.25). Although

Figure 9 Bottom panel: Proportion of survivors as a function of gall size (x) in *Eurosta solidaginis*. Dots show observed value, the solid line the fitted curve

$$\text{Survival} = 0.21 + 0.42e^{-\left(\frac{x-24.3}{3.84}\right)^2}$$

Middle panel: Frequency distribution of lag time between oviposition and gall initiation. Top panel: Reaction norms from the 16 full-sib families.

the former estimate is not significantly different from zero, the ANOVA indicated significant family effects.

Maximum survival occurs when gall diameter is approximately 24.3 mm, and hence we would expect selection to favor reaction norms that produced a gall of this size, regardless of lag time. In this regard it is significant that the greatest intersection of the reaction norms occurs at the modal lag time but gives a gall diameter of approximately 19 mm (Figure 9). Thus the fitnesses of the different families are approximately equal in the most frequent environment but are lower than the maximum fitness. Selection should act to shift this area of intersection upward, which could be done by increasing the intercepts or changing the slopes. In the former case an overall increase of approximately 4 mm would achieve the required maximization of fitness within the modal environment, but in the latter case it appears that a much greater range in slopes must be achieved. Therefore, we might expect that selection will act most strongly in a directional sense on the intercept, since the same change in all families is likely to have a greater impact on fitness than a similar change in the slope. This prediction can be tested by estimating the relative

strengths of selection on the two parameters. As predicted, directional selection was stronger on the slope than the intercept (Intercept/Slope = 4.4), but stabilizing selection acted approximately equally on the two components (Intercept/Slope = 1.4).

This study reinforces the point that the presence of genetic variation is necessary for reaction norms to evolve to their optima, but at the same time the continued presence of genetic variation remains a phenomenon that itself must be explained.

Environments with Both Stochastic and Predictable Components

The most realistic scenario of the environment is that it has both stochastic and predictable elements. Consider, for example, the problem faced by a organism in which its propagules (eggs or seeds) can survive frost, and so can overwinter, but all other stages are killed by a frost. Now suppose the season available for growth and reproduction is long enough to accommodate on average two generations. Individuals that mature early in the season will lay direct developing eggs that give rise to the second generation. Individuals of the second generation will all lay diapausing eggs that will overwinter. However, individuals of the first generation that emerge late in the season face the problem that there may be insufficient time for a second generation in which case they should lay diapausing eggs. If the season is long enough to accommodate a second generation, diapause eggs have a lower fitness than direct developing eggs, because the former give rise to only a single descendent for that year whereas the latter give rise to many descendants. In an environment in which the day of the first frost always occurred on the same day or could be predicted without error by the first generation females, there would be a sharp switch between the production of diapause and direct developing eggs. On the other hand, in general, the day of the first frost could only be assigned as a probability function: under this circumstance there will exist a period during the season during which the most fit strategy will be to lay a mixture of diapausing and direct developing eggs, the proportion depending on the reliability of the cue.

The phenomenon in which a mixture of types is produced is termed bet hedging or risk spreading. It has been explored theoretically fairly extensively, but there have been few empirical tests. In particular, risk spreading could be achieved by a strategy of avoiding risks (e.g., switching to production of diapausing eggs whenever the probability of not getting in the second generation is less than 1), which has been termed conservative risk spreading or by a single genotype producing a range of phenotypes, which has been termed diversified risk spreading. In an extensive review of insect data Hopper (1999) concluded that there is little evidence that risk spreading has been a major factor in the evolution of insect life histories. The importance of risk spreading in the evolution of life histories remains to be satisfactorily investigated.

Glossary

Bennettitales Synonymous with Cycadeoidales, an order of extinct gymnosperms composed of two families having both unisexual and bisexual reproductive structures.

Gnetales A small relict order of chiefly tropical or xerophytic gymnosperms that includes the genera *Gnetum*, *Welwitschia* and *Ephedra*.

Homology Similarity due to common ancestry.

Phylogeny The evolutionary history of species and higher taxa.

Synapomorphies Shared characteristics that define a cladistic grouping or clade.

Introduction

Only a few years ago, a meaningful understanding of angiosperm relationships and their diversification might have seemed out of reach and questions swirled around the origin with little focus. Stunning advances in molecular systematics (e.g., Palmer and Zamir, 1982), including those techniques that now allow rapid analysis of large molecular datasets (the “ratchet,” Nixon, 2003), have resulted in remarkably well-resolved assessments of within-angiosperm relationships. These advances accompanied by a much improved fossil record of angiosperms now also allow us to estimate timing in their diversification. The origin of angiosperms, however, is another matter. Just a few years ago, the angiosperms were comfortably nested in a clade called “anthophytes” with living Gnetales and extinct Cycadeoidales (Bennettitales) (Friis *et al.*, 2009). The same advances in molecular systematics that have provided valuable insights into within-angiosperm relationships and timing in angiosperm history have challenged the integrity of the anthophytes removing Gnetales to the rest of the gymnosperms. Cycadeoidales, on a closer look, may also be more appropriately grouped with other gymnosperms (Crepet and Stevenson, 2010). Thus, new methods have helped to focus our questions on angiosperm ancestry but have not answered them. There remains a gulf between angiosperms and their possible ancestors that is populated by fossil taxa with arguable transitional affinities based on logical but inconclusive assertions of connecting homologies. Nonetheless, new breakthroughs in the molecular genetics of development and exciting, if controversial, new fossils are improving the prospects for a near-term solution to what is debatably one of evolutionary biology’s greatest remaining mysteries.

In summarizing our state of understanding of angiosperm origins and diversification, it is important to note at the onset that these areas of inquiry remain open to controversy even as exciting new modes of investigation and analysis have become available. Perhaps because of the importance and scope of the questions that remain unresolved concerning angiosperm relationships and radiation, these questions often inspire passionate advocates of differing points of view. Although a consensus is being approached on certain aspects of angiosperm history, and relationships among the angiosperms are better understood, others are open to controversy and change

in the face of an increasing pace of investigation. Thus, this may be regarded as a status quo summary and change in our understanding of these important biological questions is highly probable in the near future.

Flowering Plants and the Abominable Mystery

The flowering plants are preeminent among vascular plants in numbers of species (250,000–300,000), they define terrestrial ecosystems at most latitudes, and exhibit more morphological diversity than any other group of plants. Economically, they are of primary importance as food, fodder, fiber, and building materials, in addition to serving as drug sources. It is thus interesting that, of all plant groups, they have the most elusive evolutionary history and, until recently, perhaps have been the most poorly understood with respect to their interrelationships.

The uncertainty surrounding angiosperm origin extends to the nineteenth century when early paleobotanical studies relied on gross morphological similarities in assigning affinities to angiosperm fossils. This approach resulted in skewed identifications, giving the appearance that apparently modern taxa were present relatively early in the fossil record, and suggesting a rather abrupt appearance of modern angiosperms. This apparent burst of modern taxa without any identifiable preceding ancestral lineage led Darwin to observe, in a now famously hackneyed quote from a letter to Heer, that the origin of angiosperms was both an “abominable mystery” and “a perplexing phenomenon” (Darwin, 1903; Friedman, 2009).

Since the nineteenth century, approaches to understanding the origin and diversification of the angiosperms have depended on paleobotany, systematics methodologies, and molecular genetics successively and, as they became available, in combination. New developments in each of these areas have increased our understanding of angiosperm diversification and relationships (Crepet and Niklas, 2009), but interestingly, have deepened the uncertainty surrounding angiosperm origin. Even with valuable new techniques and methodologies, the angiosperm fossil record remains central to understanding their origin. Beyond certain generalizations, ancestral types cannot be reconstructed from phylogenetic

trees either by character optimization on morphology/structure-based trees or by inference from trees based on molecular data alone (gene sequences). Yet, although the fossil record holds the best potential for identifying angiosperm ancestors, it has failed to resolve questions surrounding angiosperm origin. In addition, at its face value – that is based on the totality of literature on the angiosperm fossil record – it has been proven unreliable for documenting angiosperm diversification because, historically, the purported affinities of many angiosperm fossils have not been based on sufficiently rigorous analyses and are unreliable in estimating the timing (Crepet *et al.*, 2004).

Studies of Diversification

One must be selective in attempting to derive a reasonably accurate picture of angiosperm diversification from published fossil evidence. Criteria used to identify the affinities of particular fossil taxa should conform with those used in establishing the relationships among the living ones today, that is, fossils must have a sufficient number of key characters (synapomorphies) to warrant identification via phylogenetic analysis. Developments in both paleobotanical and systematic studies have made it practical to employ these criteria in confirming fossil affinities. Increasingly careful comparative analyses of angiosperm fossils began in earnest in the 1960s with emphases on leaf venation, epidermal features, and pollen characters (Dilcher, 1974; Hickey, 1973; Walker and Doyle, 1975; Hickey and Wolfe, 1975). In the mid-1970s, fossil flowers, important because of their taxonomic and reproductive implications, became serious and sustained objects of study, resulting in a more informative fossil record of angiosperms and a better understanding of their diversification pattern (Crepet *et al.*, 2004; Crepet, 2008; Crepet and Niklas, 2009).

Studies of Angiosperm Origin

In recent years, new analytical methods, new data sources, and newly discovered fossils have brought us much closer to an understanding of the origin of angiosperms. Nevertheless, the origin of angiosperms remains unresolved. For example, even though there has been a breakthrough in identifying a number of genes controlling floral development in angiosperms and some of these genes have been identified in nonangiospermous taxa, such discoveries have not yet provided definitive insights into angiosperm origin. So far, there have been no successful attempts to reconstruct transitional morphologies linking angiosperms to gymnospermous ancestors based on our understanding of genes controlling floral development. Although phylogenetic studies using molecular data have refined our understanding of the relationships among and within all major clades of plants, including angiosperms, they have also separated gymnosperm and angiosperm lineages at the base of the phylogenetic tree of extant seed plants (e.g., Chaw *et al.*, 2000). In doing so, these studies have distanced modern Gnetales (composed of the genera *Gnetum*, *Welwitschia*, and *Ephedra*) from the angiosperms. The Gnetales are now considered to be more closely allied to other gymnosperms despite the shared suite of

morphological/structural characters that was once interpreted as evidence of a close relationship with angiosperms (e.g., Crane, 1985; Doyle and Donoghue, 1986; Nixon *et al.*, 1994; Rothwell and Serbet, 1994). This complexity has further deepened the mystery of angiosperm relationships with other seed plants (angiosperm origins).

This separation between angiosperms and Gnetales is both interesting and perplexing because of the apparent conflict between the previous morphological analyses that consistently grouped Gnetales with angiosperms in the anthophytes (Crane, 1985; Doyle and Donoghue, 1986; Nixon *et al.*, 1994; Rothwell and Serbet, 1994; Rothwell *et al.*, 2009) and those more recent analyses based on gene sequence data that separate all gymnosperms from angiosperms early in the diversification of the seed plants (e.g., Chaw *et al.*, 2000; Mathews, 2009). Given the implications of nucleic acid sequence based phylogenies, the characters in Gnetales that putatively linked them with angiosperms (e.g., including net-veined leaves, a form of double fertilization, bisexual reproductive structures (Figure 1), the presence of vessels in the wood, and sterile structures surrounding ovules) are now

Figure 1 *Gnetum gnemon* pollen-bearing organs. Note that whorls of synangiate pollen-bearing organs subtend whorls of (sterile) ovules illustrating the juxtaposition of structurally male and female reproductive organs in the Gnetales. widely regarded as parallel developments. Yet, in the face of apparently overwhelming evidence from numerous molecular analyses, there are stalwarts who still advocate the relationships based on morphology trees, and new fossil evidence has been cited in support of the anthophyte concept (Friis *et al.*, 2007). However, more recent analysis of the data presented by these authors does not add support to the anthophyte clade concept (Rothwell *et al.*, 2009). At the same time, comparative studies of within-modern angiosperm relationships have also failed to illuminate angiosperm ancestry because the modern representatives of the earliest branching lineages of angiosperms, *Amborella* or the Nymphaeales, depending on the analysis, do not have characters that provide insights into the relatives of angiosperms (i.e., they do not share significant characters with any nonangiospermous taxa). Given that no living taxon can be identified as linking angiosperms and other seed plants, and that the reconstruction of possible links based on our existing understanding of character distribution and genes controlling floral development have not been possible, hope for a solution remains with the fossil record. Fossil evidence, however, is problematic and as with comparative studies of extant taxa, there are no obvious fossil intermediates between the gymnosperms and the angiosperms, leaving the field open to speculation and a variety of competing hypotheses.

Why has the Fossil Record Failed So Far?

Why has the fossil record failed us with this most important group of plants despite the fact that it is replete with transitional mosaics (missing links) between other groups of vascular plants? There are no generally accepted fossil intermediates between angiosperms and other seed plants, and attempts to identify fossils that represent extinct taxa transitional to angiosperms are complicated by a number of issues. A traditional difficulty has been attempting to identify an angiosperm sister group on the basis of the preserved morphological/structural characters. A weakness to this approach lies in the possibility that underlying genetic changes could have been involved in such transformations without leaving a sequence of morphologically expressed connecting intermediates.

Thus, from the onset one must acknowledge the possibility that there were no morphoclines leading from gymnosperms to angiosperms, that is, that actual intermediates may not be recognizable on morphological grounds even if discovered in the fossil record. If so, clarification of angiosperm origin must await advances in understanding more completely the genetics underlying floral development, factors controlling gene expression, and the distribution of these genes in existing seed plants. But assuming that intermediacy was expressed in a morphological transition to angiospermy, and that fossils representing transitional taxa have either been undiscovered or gone unrecognized, there are a number of relevant questions, including: What subset of characters is required to reasonably identify a potential angiosperm sister group and for that matter what subset might be necessary even in identifying a very early angiosperm? What combinations definitely indicate a relationship to the angiosperms? And, given that

preservation is most often incomplete limiting the number of available characters, which characters are definitive indicators of angiosperms? Given these questions, it has been traditionally difficult to avoid subjective judgments in evaluating the significance of fossils that are possible angiosperm ancestors. However, questions regarding relationships of fossils can now be addressed more objectively by phylogenetic analysis, a methodology that precisely determines relationships among taxa and purportedly minimizes the influences of subjective interpretation. However, even with the advent of phylogenetic analysis, there has been no consensus on the closest fossil relatives of angiosperms.

There are a number of plausible reasons for this disappointing situation. Firstly, in addition to the issues cited above (*see* Introduction), there are general problems inherent to fossil evidence: the record is incomplete, reflecting variation in optimum conditions for fossilization through time, and is undersampled. In addition, there have been relatively few paleontologists and available fossil sites for investigation. Furthermore, the fossil record has been poorly sampled in the time periods likely to be important in discovering extinct angiosperm relatives (Jurassic–Early Cretaceous). In addition, given the morphological gap between angiosperm reproductive structures and all the known gymnospermous ones (fossil and modern), and in the absence of a generally accepted transformation series (or morphocline) linking key nonangiospermous reproductive structures with angiospermous ones, it is difficult to identify characters in nonangiosperms that can be regarded as homologous with angiosperm defining characters. For example, based on morphological transformation models, multistep and tortuous transformations are necessary to support hypotheses linking various (and virtually all possibly ancestral) fossil taxa to the angiosperms (e.g., *Cycadeoidea* (Bennettitales), *Corystospermaceae*, *Glossopteridales*, and *Caytoniaceae* (a good example is in the sometimes hypothesized transition from the caytonian cupule to anatropous ovule + carpel of angiosperms)). Thus, although phylogenetic analysis has provided a powerfully objective tool for determining relationships, the assignment of character equivalencies needed for phylogenetic analysis (the determination of homologies) remains highly subjective in the absence of unequivocal links and prone to the influence of the currents of tradition, and so there is no consensus on extinct angiosperm relatives (Taylor and Taylor, 2009).

Fossil Evidence – Status Quo

What is the status quo in our understanding of fossil evidence? In approaching the fossil record, as with evaluations of extant taxa that might be germane to angiosperm origin, we might consider what to look for in addressing the question of angiosperm origin and then consider appropriate fossils and the implications of these fossils. In general, there are two possible subgroups that would be relevant to angiosperm ancestry: fossil taxa that are clearly not angiosperms, but that have synapomorphies (shared derived characters) that may link them to angiosperms; and early angiosperm fossils that may possess characters linking them to nonangiospermous ancestors.

Potential Angiosperm Sister Groups (Ancestors)

In the first category above (nonangiosperms), known fossils include principally:

The Mesozoic seed fern *Caytonia* (Figure 2). *Caytonia* was originally described as an angiosperm because the ovule-enclosing cupules were confused with enclosed carpels (Thomas, 1925). Even after the discovery that the cupules were not closed led to the conclusion that *Caytonia* was a seed fern (Harris, 1940, 1964), the taxon continued to be linked with angiosperms. Some authors felt this because of a number of similarities such as net-veined leaves (although *Caytonia* veins are not hierarchical by size like those of the angiosperms), stomatal subsidiary cell configuration (paracytic – a generalized character occurring in a number of taxa) and, most significantly, by a superficial similarity between the adaxially incurved cupules containing numerous seeds and the anatropous ovule characteristic of many, but not all angiosperms (interestingly not found in *Amborella*, the taxon at the base of most recent angiosperm phylogenies). The proposal equating the cupule of *Caytonia* with an anatropous angiosperm ovule posits that the cupule itself represents the second integument of the angiosperm ovule (even though not all angiosperms are bitegmic), and requires several additional morphological changes, including the reduction of ovules within the cupule to one, and the *de novo* origin of the carpel. Thus, beyond what has been observed in *Caytonia*, there are several steps needed for the transformation, and yet there is no fossil evidence of any intermediates to support the hypothesized transformation. Furthermore, the combination of ovules with adaxially disposed micropyles and subtending sterile structures evocative of anatropy is not unique to the Caytoniaceae in gymnosperms or

even among Mesozoic seed ferns (Taylor and Taylor, 2009). Thus, although plausible and possible depending on underlying genetics, this proposed homology is not compelling enough to be regarded as solving the issue of angiosperm origins, especially given the distinctly pinaceous saccate pollen found in *Caytonia* (adding additional steps to any transformation).

The Cycadeoidales (or Bennettitales, Figure 3). This is the other major fossil group often associated with angiosperms. One of the principal genera of the order, *Cycadeoidea* (Figure 3), was thought to be a link between angiosperms and gymnosperms when it was first found to have bisexual reproductive structures (Figure 3). Subsequently, its relationship to angiosperms has been debated. Although the Cycadeoidales are part of the anthophyte clade recognized in morphology-based phylogenetic analyses, the integrity of the group is in question based on molecular systematics analyses and recent reanalyses of morphology-based trees challenge the position of Cycadeoidales in an anthophyte clade (Figure 4; Crepet *et al.*, 2011; Crepet and Stevenson, 2010). Nonetheless, as with *Caytonia*, there are some appealing similarities between angiosperms and Cycadeoidales. The cycadeoidalean genera *Cycadeoidea*, *Wielandiella*, and *Williamsoniella* each have bisporangiate cones with an ovulate receptacle subtended by variously pinnate microsporophylls bearing synangiate pollen organs that are in turn subtended by sterile bracts. The congruence between this arrangement of organs and the succession found in the typical angiosperm flower (carpels surrounded by stamens surrounded by sterile petals/sepals) raises the question of affinities: are the similarities based on homology or parallel evolution?

These similarities are even more compelling in light of other shared characteristics including some pollen characters, stomatal subsidiary cell configuration, and dicotyledonous

Figure 2 (a)–(c) *Caytonia*. (a), (b) SEM photographs of the seed-bearing cupules. (c) Line drawing of cupule-bearing axis. (d) *Caytonia* leaf (*Sagenopteris*) venation pattern. Part 5. Stratigraphic relations of the plant beds. *Meddeleser om Grønland, Kjøbenhavn* 112(2): 1–114.

Figure 3 A reconstruction of the bisporangiate cone of the genus *Cycadeoidea* showing pollen-bearing organs subtending a conical ovule-bearing receptacle. This arrangement of pollen-bearing organs and ovules is unique to cycadeoids, angiosperms, and is approached in Gnetales.

embryos, although such embryos are not unique to angiosperms and cycadeoids and are not even ubiquitous within angiosperms, and, transformation of a cycadeoid flower would be complex and once more require the *de novo* evolution of a carpel, dramatic reduction of the microsporophylls and a change in symmetry in both pollen organs and ovule-bearing structures. Moreover, careful comparisons between Cycadales and Cycadeoidales reveal more similarities and fewer differences than previously recognized in analyses leading to the identification of an anthophyte clade. Recent analyses that incorporate these observations suggest closer ties between Cycadales and Cycadeoidales in a clade that also includes Mesozoic pteridosperms (Crepet and Stevenson, 2010) (Figure 4). Yet, even if Cycadeoidales turned out to be more closely related to Cycadales than previously thought as indicated by this analysis, a link between these lower seed plants and angiosperms might not be out of the question in the context of the early split in seed plants between the angiosperm and gymnosperm lineages, that is, any group at the base of gymnosperms could plausibly be the one most closely related to the angiosperms.

Corystospermaceae: These Mesozoic seed ferns have been the focus of an attempt to synthesize knowledge of MADS Box floral development genes, and fossil evidence in hypotheses on angiosperm origin that suggest ways that corystosperm pollen-bearing organs might be transformed into bisexual angiosperm flowers. This hypothesis draws attention to the importance of underlying genetics and to the possibility that transitional morphologies have not been discovered in the fossil record because they never existed. This general approach will become more important as details of genes controlling floral development are increasingly revealed and when there is a better understanding of the distribution and nature of these genes among extant taxa (Frohlich and Parker, 2000).

Glossopteridales: The seed-bearing structures of glossopterids were known for a long time from only relatively poorly preserved impression fossils. These fossils were alluringly carpel-like in appearance and quite variable in morphology. They are now more completely understood based on careful studies of well-preserved petrified fossils from Australia and Antarctica (e.g., Gould and Delevoryas, 1977). Although early suggestions that glossopterids might have been related to the angiosperms were based on putative homologies between the seed-bearing organs of *Glossopteris* and the carpels of angiosperms and on their superficially common net-veined leaves (Retallack and Dilcher, 1981), glossopterids have not been placed near angiosperms in comprehensive phylogenetic analyses (e.g., Crane, 1985; Doyle and Donoghue, 1986; Nixon *et al.*, 1994) (Figure 4).

In summary, there is no clear consensus on the closest fossil relatives of angiosperms, with unavoidably subjective assessments of homology clouding the results of the various, sometimes conflicting phylogenetic analyses. As it stands, there are a number of possibilities that cannot be definitively ruled out because the genetics underlying the development of key reproductive structures is poorly understood and available fossil (and other) evidence does not favor one fossil taxon over another (e.g., Taylor and Taylor, 2009).

Early Angiosperms – Imagined and Real

The second category of potentially informative fossils relevant to angiosperm origin, that is, early putative angiosperm fossils, includes a number of taxa. Some of the better known ones are interesting, but they are not understood well enough to be unequivocally regarded as angiospermous because the fossils have too few characters to be convincingly placed with angiosperms in phylogenetic analysis. Notable among these fossils are several of the Triassic age, and thus they are older than the earliest generally accepted angiosperm fossils (these are Lower Cretaceous). Such fossils include *Furcula*, an organ taxon for dichotomous leaves with net venation (Harris, 1932), isolated pollen grains with angiospermous pollen characteristics (Cornet, 1989a), and a taxon first described from leaves (*Sanmiguelia*) but later descriptions included purportedly related reproductive structures (*Axelrodia*) as well as almost entire plants (Brown, 1956; Cornet, 1986, 1989b; Tidwell *et al.*, 1977). *Sanmiguelia* is intriguing because the plicate fan-shaped leaves are similar to those of some extant monocots (e.g., Liliaceae). The fossils, however, are poorly preserved and the

Figure 4 Phylogeny of seed plants based on a revised and expanded morphology matrix illustrating the position of Caytoniales, Glossopteridales and the instability of the Cycadeoideales (Bennettitales).

reproductive structures have been unconvincingly reconstructed. In the absence of sufficient data and analyses, there is no consensus on their significance at this time.

A relatively recently discovered fossil, *Archaeofructus*, is one of the most potentially important of the known fossil angiosperms. Although there is no doubt of its angiospermous nature, there is a debate as to its phylogenetic position. The question at issue: is it the sister group to all remaining angiosperms or is it nested within an extant taxon? (Friis *et al.*, 2003; Endress and Doyle, 2009). *Archaeofructus* is significant because it is completely preserved with reproductive organs attached to the vegetative part of the plant and because it comprises an unusual set of characteristics. Initially reported as Jurassic in age, it is now regarded as Lower Cretaceous and although early for an angiosperm, it is not uniquely the oldest of generally accepted angiosperm fossils. From specimens preserved in their entirety, it is obvious that *Archaeofructus* was an aquatic plant (the leaves have air bladders), and that it lacked the typical organization of angiosperm flowers because

naked carpels are only subtended by stamens along elongate axes. There is no evidence of any kind of floral envelope. *Archaeofructus* has been interpreted both as an angiosperm that is a sister group to the rest of the angiosperms (Sun *et al.*, 1998) and as an aberrant member of the Nymphaeales, morphologically distinct from any modern member of that group with flowers that are so highly reduced that there is no evidence of usual angiosperm floral organization (Friis *et al.*, 2003). The latter interpretation is based on a phylogenetic reanalysis of the Sun *et al.* (2002) character matrix (Friis *et al.*, 2003). However, this reanalysis included a mistake in coding of a significant character (leaves) in a taxon that was added to the original analysis (*Cabomba*). When the matrix is corrected to reflect actual variation in *Cabomba* leaf morphology, subsequent analyses uniformly indicate that *Archaeofructus* is the earliest branch in the angiosperm lineage. Once again it becomes a sister group to the angiosperms in 100% of the shortest trees. It is never placed with *Cabomba* or in the Nymphaeales, thus conforming with the results of Sun *et al.*

(2002) and supporting original interpretations of its reproductive structures as innately simple and not simple owing to the process of evolutionary reduction that might have been associated with adaptation to an aquatic environment. In another recent analysis (Endress and Doyle, 2009), *Archaeofructus* also comes out with Nymphaeales, but the analysis is fragile and there are coding issues that call the results into question that, when corrected, again result in a phylogeny placing *Archaeofructus* at the base of the angiosperms (Crepet *et al.*, 2011). Even so, it is likely that more characters (details of pollen structure, etc.) and subsequent supporting analyses will be needed to achieve a consensus view on the phylogenetic significance of *Archaeofructus*. If confirmed as representing the earliest branch in the angiosperm lineage, *Archaeofructus* would provide some unique insights into the nature of early angiosperms, but based on our present understanding of its morphology, would not unambiguously link angiosperms to any group of nonangiospermous seed plants. In general aspect, *Archaeofructus* is evocative of seed ferns, but the gap between known seed fern reproductive structures and those of *Archaeofructus* is significant, and evidence for transformations such as those invoked in the putative transition from *Caytonia* to an angiosperm is missing from the fossil record.

Should additional characters and analyses continue to support the phylogenetic placement of *Archaeofructus* on the stem lineage below all other angiosperms, the implications of the aquatic habit in *Archaeofructus* and questions as to whether an aquatic bottleneck was involved in the consolidation of angiospermous reproductive features will undoubtedly be pursued (e.g., Did carpels evolve in response to selection for protecting developing ovules while still submerged? Is insect pollination more efficient at the water level? What are the implications for identifying possible angiosperm ancestors? Were there earlier stem lineage angiosperms that were not aquatics?).

Conclusions – Angiosperm Origin

There is no convincing evidence as to the closest group of nonangiospermous seed plants living or fossil. Recent developments have raised questions and revealed aspects of seed plant relationships that narrow the search and pose questions that can be foci of more intense investigations. Fossil studies have the potential for identifying the ancestral angiosperm lineage, especially in the context of molecular genetics, but, in spite of exciting new developments, the issue of angiosperm origin remains unresolved.

Angiosperm Diversification

Analytical Techniques Relevant to Understanding Diversification

Ideally, increasingly complete and reliably identified fossil evidence and advances in molecular systematics can be combined with the aim of improving our understanding of angiosperm diversification. Although timing was once taken at face value from the fossil record, today we recognize that such an approach is compromised by a literature that is replete with

misidentifications based largely on superficial comparisons between fossil angiosperms and the corresponding organs of modern angiosperm taxa. A selective approach to fossil evidence focusing on accurately identified fossils would improve our understanding of angiosperm history and would provide a better understanding of the diversification of the angiosperms than an uncritical review of the literature. However, the fossil record is incomplete and such a strict interpretation of the literature would leave many gaps in our understanding of the timing of events in angiosperm radiation. The advent of molecular systematics provides better ways to estimate both diversification pattern and timing, especially now that it has engendered a growing consensus on the relationships among modern angiosperm taxa. There are a number of ways to combine phylogenies based on gene sequence data and the fossil record of angiosperms to reveal timing in angiosperm diversification. Different methods have produced different estimates and a lively debate is underway as to which promises to be the most accurate. A “consensus phylogeny” may be used either with selected fossil evidence in molecular clock-derived models (e.g., Sanderson, 1997; Sanderson *et al.*, 2004) or alternatively, in conjunction with the carefully screened entire fossil record of angiosperms in the “minimum-age node mapping” methodology (Crepet *et al.*, 2004). Depending on the details of the applications, the two methods can produce dramatically contrasting estimates of timing in angiosperm history or within particular clades. Depending on the model and the analysis, there is considerable variation in the estimation of timing in angiosperm history, and some of this variation is related to the specific methods used to calculate timing and some to the choice of fossils used in calibration. For these reasons, estimates based on molecular clock-derived models have been subjected to intense scrutiny and criticism (Graul and Martin, 2004), but these clock-based methods are still evolving with different approaches showing promise (Sanderson *et al.*, 2004; Lavin *et al.*, 2005). The results of certain analyses are roughly congruent with timing suggested by fossil evidence alone, but timing estimates based on other analyses project much greater ages for various lineages or for the entire angiosperms than those revealed by the fossil record (Savolainen *et al.*, 2000). These discrepancies in timing angiosperm diversification have significant implications because differences in perceived timing affect our understanding of important events in angiosperm evolution and therefore of factors that may have been relevant to angiosperm success (e.g., possible synergy with insect pollination, animal fruit dispersal, and climatic conditions). Such differences also affect our understanding of angiosperm biogeography (e.g., timing is important in evaluating the potential significance of various land bridges to angiosperm biogeography or in estimating the effects of vicariance; Tiffney, 2008).

One of the major criticisms of analyses that have predicted greater ages for taxa than those verifiable by fossil evidence is that these discrepancies have not been satisfactorily explained except by the untested premise that the record itself lags the pattern of evolution, often dramatically. This notion is based on the assumption that there is a significant delay between the origin of a new taxon and its first appearance in the fossil record owing to the time it takes a new taxon to reach a population size and distribution that make deposition,

preservation, and discovery likely. This explanation of lagging fossil evidence is unconvincing because the time needed for population size to grow to the point where preservation (and, ultimately, fossil discovery) is likely is going to be miniscule relative to geologic time. Thus, discrepancies in timing on the scales projected by some clock-based models (tens of millions of years in some cases) seem unlikely given that a new taxon may have increased in population size and range to the point where preservation in the fossil record was likely in an interval that would be essentially instantaneous in the frame of geologic time (Burnham, 2008). There are cases where preservation seems unlikely in widely dispersed herbaceous taxa that are insect-pollinated, for example, and instances such as these are partially responsible for gaps in the fossil record that may be addressed by the methods discussed above (see Analytical Techniques Relevant to Understanding Diversification).

As molecular clock-based models continue to be refined and are becoming more accurate, an alternative and complementary way to combine fossil evidence with molecular systematics-generated phylogenies of living taxa already exists in “minimum-age node mapping” (Crepet *et al.*, 2004). Minimum-age node mapping methodology is based on the straightforward premise that, in phylogenetic context (and the success of the method depends on the framework of an accurate phylogeny for angiosperms made possible through molecular systematics such as that of Soltis *et al.*, 2000), a taxon’s immediate ancestor (i.e., the taxon represented by the node proximally subtending the taxon) has to be as old or older than that taxon. By plotting reliably identified fossils on a consensus molecular systematics phylogeny, this methodology provides minimum times of appearance even for taxa that do not have fossil records (of course, such predictive power is also a goal of variously modified molecular clock models).

Although some clock-based estimates of timing in angiosperm evolution seem outlandish when compared with the fossil record, others, using reliably identified fossils and refined methodologies (e.g., Lavin *et al.*, 2005; Magallon-Puebla *et al.*, 1999; Sanderson *et al.*, 2004), have generated results that are more consistent with those of minimum-age node mapping. As increasing numbers of reliably identified fossil taxa are used in calibrating such models, and as the models themselves become further refined, results might be expected to converge with the fossil record of angiosperms and might also be effectively used for filling in gaps in understanding timing in particular clades that have relatively good fossil records (as in Lavin *et al.*, 2005). Currently, the results of node mapping methodology provide the most conservative assessment of timing in angiosperm radiation. Given the interest in improving molecular clock-based timing models, however, and their popularity (easy to use, appealing (especially rate smoothing) premise, they fill in the gaps in the record), assessments of timing are likely to be in flux and somewhat controversial in the near future.

Major Features of Angiosperm Diversification

As consensus is approached in estimates of the timing and pattern of angiosperm diversification, major events in the

evolution and radiation of the flowering plants can be conservatively, but reliably, placed in a temporal perspective allowing for the evaluation of various ecological/evolutionary hypotheses that have been proposed to explain angiosperm success (Crepet and Niklas, 2009).

Early Angiosperm Diversification

Timing and diversification in angiosperm history is summarized in the phylogenies presented in Figures 4–6 based on a subset of carefully identified angiosperm fossils plotted according to minimum-age node mapping methodology using the phylogeny of Soltis *et al.* (2000) and Crepet *et al.* (2004). The early radiation of bona fide angiosperms illustrated in Figures 4 and 5, began in, and then characterized the Lower Cretaceous. In Figure 4, the emphasis is more on basal angiosperms followed closely and overlapping temporally with the subsequent radiation of the remaining tricolpate pollen-bearing clades (the “eudicots”) illustrated in Figure 5. The numbers in the figures represent ages of the clades in millions of years. Numbers on a terminal branch represent the age of the terminal taxon (e.g., Chloranthaceae 98). Terminals on unnumbered branches or clades without numbers (e.g., *Hedycarya* + *Peumus*) have the same minimum ages as the node below. *Archaeofructus* is not included in the cladogram, but as a sister group to the rest of the angiosperms, a position now favored by the preponderance of available evidence, it would push back the timing of angiosperm radiation (still within the Cretaceous) based on bona fide fossil evidence but would not affect the timing in the rest of the phylogeny.

The estimates illustrated in Figures 4 and 5 suggest extensive diversification in several important angiosperm clades during the Lower Cretaceous to Turonian interval that included magnoliids, monocots, and several tricolpate clades. The possibility of an Early Cretaceous monocot diversification is supported by the presence of Triuridaceae floral evidence in the Turonian (because the triurids represent a derived taxon), but Early Cretaceous monocot diversification is not reflected by the mega or mesofossil records. Although many reports of pre-Turonian monocot pollen are based on characters that are not exclusive to monocots (Gandolfo *et al.*, 2000), a recent report of dispersed but distinctive Araceae-like pollen (Friis *et al.*, 2004) suggests that at least some Early Cretaceous palynomorphs represent monocots, a finding that would be consistent with node mapping projections of monocot minimum ages (Figure 5).

The occurrence of numerous platanoid fossil leaves, flowers, fruits, and pollen among the oldest representatives of the “tricolpate” clade (or “eudicots” of some authors) at about 100 Ma is consistent with, and even slightly younger, than the age of the sister clade of the tricolpates + Ceratophyllum based on fossil evidence of winteraceous pollen (Walker *et al.*, 1983) from the Early Cretaceous of Israel (4105 MyBP).

Minimum-node mapping methodology, like molecular clock-based models, can calculate minimum ages for the stem groups of some families that lack a fossil record revealing that the minimum calculated ages for some families are greater than the ages of the oldest known fossils for the group. Sabiaceae, for example, has a calculated minimum age of 98 MyBP for its divergence from other extant angiosperms,

Figure 5 Minimum ages for major "basal" lineages of angiosperms (113–90 MyBP) based on the best available fossil evidence mapped onto the three-gene 560 angiosperm tree (Soltis *et al.*, 2000). The tree has been collapsed to show major clades of interest. Numbers in brackets following a name indicate the number of distinct sequences that were used in the original molecular analysis.

based on fossils assignable to other families (Figure 5), even though the oldest putative fossils known for Sabiaceae seeds from the Late Cretaceous, are at least 27 My younger (Knobloch and Mai, 1986).

As with all minimum ages for clades predicted by minimum-age node mapping or other (molecular clock-based) models, this does not imply that the "crown group," in this instance modern Sabiaceae, had diverged by this time, but that the divergence of Sabiaceae from other extant angiosperms occurred at least 98 Ma. In fact, and again a good example for similar instances with other clades, the modern family may

have diverged much more recently, and the perceived hiatus may be explained by numerous factors, including lack of identifiable features of modern Sabiaceae in the early members of the clade (e.g., as in legumes), preservational bias owing to morphology, mode of pollination, ecological distribution, or random events influencing the preservation of fossils (Crepet *et al.*, 2004).

Rosid 1 Clade Diversification

One of the most impressive aspects of angiosperm diversification is the rapid radiation of the Rosid 1 Clade – the clade

Figure 6 Minimum ages in million years before present for major lineages within the tricolpate or "eudicot" clade (some collateral groups not shown, such as Platanaceae, Buxaceae; see **Figure 5**).

that includes Rosaceae, Malpighiaceae, and a host of other families traditionally placed in either the Rosidae or the "Higher Hamamelididae" (**Figure 7**). Beginning at least by the mid-Cretaceous, Rosid 1 diversity was already well established

by the Turonian with the existence of two firmly identified fossils in the lower part of this subtree (Cunoniaceae and Clusiaceae) allowing estimates of the minimum divergence times for the stem lineages of several families owing to the

Figure 7 Minimum ages in million years before present of taxa within the "Rosid I" (sensu APG II, 2003) clade.

pectinate topology. The divergence of the stem groups for Oxalidaceae, Elaeocarpaceae s.s., Eucryphiaceae, and Cunoniaceae can be estimated at 73 MyBP, and thus, any modern species in those families has a minimum divergence of

73 MyBP from any other angiosperm species not in the same family. Likewise, a minimum age of 90 MyBP for the divergence of the stem group of Malpighiaceae can be estimated based on Clusiaceae fossils from the Turonian of New Jersey

Figure 8 Reconstruction of the fossil flower *Paleocclusia chevalieri* (Crepet and Nixon, 1998). Illustration courtesy of M. Rothman.

(Figure 8; Crepet and Nixon, 1998; also note Figure 9 for an example of the kind of preservation that has improved our understanding of fossil floral history).

Another important clade within the “Rosid I” group includes Rosaceae, Fabaceae, Urticales, Cucurbitales, and the families formerly included in the “Higher Hamamelididae” (e.g., Fagaceae, Nothofagaceae, Juglandaceae, Myricaceae, Betulaceae, and Casuarinaceae). This clade includes a diverse assemblage of economically important taxa with an exceptional fossil record. The minimum age of the stem group of the clade that includes Rosaceae and Fagales but excludes Fabaceae and Polygalaceae is estimated at 94 MyBP, whereas the first identifiable fossil of Fabaceae is from the Tertiary, ca. 51 MyBP (Herendeen and Crane, 1992), or at least 40 My after the minimum estimated divergence for the clade. It should be noted in this context that strongly zygomorphic flowers are not present in the best known Late Cretaceous deposits, and the radiation of both Polygalaceae and zygomorphic Fabaceae (i.e., papilionoid and caesalpinoid flowers) may have been a Tertiary event, possibly in response to selective pressures associated with the increased availability of specialized hymenopterous pollinators (apparently available at some level since at least Turonian times, Crepet, 2000). It is likely that members of the “stem group” subtending Polygalaceae–Fabaceae were actinomorphic and closely resembled modern Rosaceae, and thus identification of such taxa would be problematic without extensive characters for evaluation as might not be available in fossils (Lavin *et al.*, 2005).

The extensive record of the *Normapolles* palynomorphs in the Late Cretaceous (e.g., Christopher, 1979; Schönenberger *et al.*, 2001) seems to reflect diversification of the Juglandales lineage, which is well nested within the “Fagales” (sensu the APG II, 2003). Although *Normapolles* palynomorphs are diverse and difficult to place taxonomically from the characters of the pollen alone and there are only a few cases where pollen has been found in inflorescences, there is little doubt that at least some of the *Normapolles* palynomorphs are correctly placed in the broad clade that includes Juglandaceae, Betulaceae, and Myricaceae (Crepet *et al.*, 2004), implying a

Figure 9 An example of the exquisite preservation by charcoalification that has added so much to our understanding of the angiosperm fossil record. This 90 My old flower, *Pentapetalum trifasciculandricus* (Martinez-Millán *et al.*, 2009) related to modern Theales, is three dimensionally preserved and shows the preservation of delicate petals and stamens. Courtesy of Crepet and Martinez Milan, Photo by S. Sritko.

minimum age for the clade of 83 MyBP. Megafossils identifiable to those particular families do not occur until later, with the exception of cupulate Fagaceae from the Turonian of New Jersey (Crepet *et al.*, 2001; Nixon *et al.*, 2001).

Notably absent are fossils of the Cucurbitales clade, which is mostly herbaceous, and for which the stem group should have been present at least by 90 MyBP. The pattern within these clades nicely illustrates the probable effect of depositional, preservational, and ecological bias in the fossil record. The largely herbaceous and insect-pollinated Cucurbitales is essentially without a fossil record (with the exception of Tertiary fossils of the woody genus *Tetrameles* (Datisceae), Laxmanpal and Verma, 1966), whereas the concomitant “Fagales” group, which is entirely woody and mostly wind pollinated has one of the most extensive fossil records for angiosperms, in terms of leaf, pollen, and reproductive structures, beginning in the Late Cretaceous and extending throughout the Tertiary (Crepet and Nixon, 1989a, b). Another factor that might contribute to the abundance of fossil Fagaceae and other members of the woody “Fagales” clade is their tendency to form extensive dominant forests (or riparian forests), whereas the Cucurbitales (e.g., Cucurbitaceae and

Begoniaceae in particular) are generally scattered individuals with far less cumulative biomass.

Ericanae (ASTERID III) and ASTERID IV Clades Diversification

The Ericales are well represented in the Turonian deposits of New Jersey (Crepet, 2000; Nixon and Crepet, 1993), providing an estimate of 90 MyBP for the minimum divergence of that group as well as for the broader group known as ASTERID III in recent works. The term “Ericanae” is used in Figure 5 in place of Asterid III because it is more descriptive of the families that were not initially placed in Asteridae that, for the most part, lack fused corollas. The Asterid IV group includes Hydrangeales known from well-established fossils from Turonian deposits in New Jersey providing an estimate of ca. 90 MyBP for the divergence of this group.

ASTERID I and ASTERID II Clades Diversification

These groups include families that were traditionally grouped under Asteridae (Asteraceae, Solanaceae, Lamiaceae, Rubiaceae, and a host of other families that together include enormous species diversity, particularly in the tropics, Cronquist, 1981), and that typically have gamopetalous and often tubular and/or zygomorphic flowers. They are not reliably represented in Cretaceous deposits. The diversification of these asterids, with the associated floral features and various correlated often highly specialized pollination syndromes, very likely took place in the Tertiary unless early asterids were herbaceous, characterized by low population densities and were insect-pollinated and thus have gone undetected in the fossil record. Nonetheless, the apparently parallel radiation of legumes, a group with generally similarly specialized pollinators, is consistent with a radiation of asterids in the Tertiary (e.g., Herendeen and Crane, 1992; Lavin *et al.*, 2005), possibly for similar reasons.

Various complex pollination syndromes were likely to have been present by 90 MyBP given the diversity of Turonian floral morphologies (Crepet, 2000; Crepet and Nixon, 1998; Gandolfo *et al.*, 1998a, b; Nixon and Crepet, 1993). These morphologies have characteristics that imply high pollinator specificity, such as viscin threads (Nixon and Crepet, 1993), enclosed floral chambers that imply entrapment pollination (Gandolfo *et al.*, 2004), nonnectar floral rewards (Crepet and Nixon, 1998), and at least some sympetaly (Nixon and Crepet, 1993). The absence of strongly zygomorphic or bilabiate flowers at this time suggests that floral zygomorphy was, and remains, an ultimate refinement in pollination syndrome that followed the development of other features. It is worth noting that the groups that later developed zygomorphy (again, probably almost entirely in the Tertiary based on current evidence) have become some of the most diverse and successful clades of modern angiosperms, including a large portion of the asterids (I and II) as well as the papilionoid and caesalpinoid legumes. Just as striking, however, is the success and persistence of numerous clades in which zygomorphic floral presentation is absent or rare, and which generally have less-stringent pollinator specificity (or passive pollination syndromes), such as the majority of rosid and ranunculid lineages, including the mimosoid legumes.

Conclusions – Diversification Pattern

Conservative estimates of timing in angiosperm history suggest a rapid diversification of angiosperm groups between 113 and 80 MyBP, or alternatively, indicate an earlier diversification that left an extremely poor, even invisible fossil record.

The observed timing in angiosperm diversification has potential implications for understanding angiosperm success and distribution. For example, timing is critical in evaluating possible reasons for the rapid mid-Upper Cretaceous radiation of the tricolpate pollen-bearing angiosperms (the “eudicots”). Among other factors (Crepet and Niklas, 2009), this radiation appears to have been related to the availability of efficient pollinators; a relationship suggested by the timely appearance in the fossil record of characteristic floral morphologies, pollen characters, and taxa that are today specifically associated with such pollinators (Crepet, 2000; Crepet and Nixon, 1998; Gandolfo *et al.*, 1998a, b; Nixon and Crepet, 1993). This coincidence has been addressed in numerous papers and is consistent with the possibility that insect pollinators, especially those likely to demonstrate pollinator fidelity, have been important in at least one major diversification of flowering plants and ultimately have contributed to establishing their dominance in numbers of species (Crepet, 2000; Grimaldi and Engel, 2005; Crepet and Niklas, 2009).

It appears that angiosperms that developed zygomorphy, and extensively fused corollas, went through a second major radiation with highly specific insect pollinators almost entirely during the Tertiary. These groups have become some of the most diverse and successful clades of modern angiosperms and they include a large portion of the asterids (I and II) as well as the papilionoid and caesalpinoid legumes.

However, numerous clades which generally have less specific modes of pollination including the majority of rosid and ranunculid lineages have been successful in attaining great diversity and temporal duration. In the same vein, it is interesting that other major groups radiated rapidly during the Tertiary and for apparently different reasons (Crepet and Niklas, 2009). Monocots with a spotty Cretaceous record nonetheless demonstrate considerable diversity by the end of the Cretaceous and an ensuing radiation during the Tertiary that includes palms and grasses. Although Juglandales/Fagales were apparently insect-pollinated early in their history (Friis, 1983), they diversified in the Tertiary in association with climatic change, animal seed dispersal, and significant adaptation to wind pollination.

Certainly, the fossil record indicates that angiosperms had the capacity to facilitate the evolution of manifold abiotic and biotic pollination syndromes that were critical to the success of the earliest flowering plants in light of a reciprocal driving mechanism for angiosperm and animal diversifications. However, if this was the single evolutionary innovation of the flowering plants, we would expect to see a monotonically decreasing pattern in the rate of angiosperm diversification throughout the Cretaceous–Tertiary, but the available (albeit limited) paleobotanical data indicate a pattern of saltational evolution and species diversification more in keeping with repeated bursts of phenotypic and correlated behavioral innovations resulting from the evolutionary introduction of novel functional traits throughout the history of the flowering

plants (Crepet and Niklas, 2009). These include features such as polyploidy and its possible significance to speciation, the attainment of the herbaceous habit—unique to angiosperms in living seed plants, the annual habit, also exclusive to angiosperms, the allopatric speciation-promoting influence of animal-mediated fruit dispersal and numerous other adaptations (Crepet and Niklas, 2009). The obvious and enduring question remains: Why did angiosperms have the capacity to accumulate these desirable and apparently speciation-promoting characteristics? We have not yet ruled out the possibility that a relatively superior reproductive biology characterized animal mediation somehow catalyzed the acquisition of these characteristics within the angiosperm lineage.

Glossary

Homology Any similarity that is explained by common ancestry.

Monophyletic group, monophyly A group of taxa that includes all of the descendants of the most recent common ancestor for the group.

Paraphyletic group, paraphyly A group of taxa that includes some, but not all, of the descendants of the most recent common ancestor for the group.

Synapomorphy A character state that is derived relative to the ancestral state (plesiomorphy). Synapomorphies are special cases of homology that are evidence of monophyly among the taxa that bear them relative to taxa that bear the plesiomorphic state(s).

Historical Overview

In the late eighteenth century, taxonomy became stabilized with the work of Linnaeus and others, and the modern hierarchical system of classification (often called the Linnean system) became standard. Hierarchical classification systems in the late eighteenth and early nineteenth centuries were often illustrated with treelike diagrams, but in general these were not intended to show evolutionary relationship and should not be interpreted as such. Following Darwin and the ultimate acceptance of evolution as the explanation for the diversity and variation of life, efforts began to produce phylogenies (diagrams of higher level evolutionary divergence among taxa), which also were often presented as treelike diagrams. The methods by which these early phylogenies were produced varied, most often based on a combination of raw similarities among taxa and either implicit (or explicit) ideas about the way in which characters had evolved. For example, Bessey in the early twentieth century published a list of dicta indicating trends in morphological characters of flowering plants (e.g., flower parts primitively with many parts, becoming fewer) and used these dicta as an implicit means of deriving phylogenies. Anecdotal theories about character evolution have been utilized by many systematists as an explicit or implicit basis for major phylogenies even to the present day (e.g., Cronquist, 1981).

Early phylogenies were usually considered independently from systems of classification, or classifications were only partially based on the results of phylogenetic analysis. One of the most prominent features of classifications from this period that persists in many current classifications is the recognition of paraphyletic groups (see below).

In a modern discussion of phylogeny, there are three main aspects that need to be addressed. First is the issue of how the phylogeny is derived: the source of evidence and how that evidence is analyzed. Second, there is the nature of the resulting phylogenetic diagram, or pattern, and what information such a diagram conveys. Third, there is the

relationship between a phylogenetic system (a phylogenetic tree) and a classification that may or may not be derived from such a phylogenetic pattern. All of these issues remain controversial at some level, with different workers taking different combinations of views on each topic. While some may view these controversies as overwrought, one healthy consequence for science is the competitive improvement of methods and the need for explicit theoretical justifications by all participants in these arguments.

Modern Phylogenetic Analysis

Beginning with the popularization of the works of Hennig in the late 1960s and early 1970s, the idea that raw similarity should be the basis for phylogenetic reconstruction was quickly overturned. One might refer to this as the “cladistic revolution.” By the mid-1980s Hennig’s notion that only special similarities, or synapomorphies, should be used to reconstruct relationships had become the dominant force in phylogenetic analysis. Although one still finds phenetic analyses published, these are often focused on infraspecific patterns where cladistic methods have not yet been fully developed. The vast majority of phylogenetic analyses in the late 1980s to the present were undertaken with cladistic methods, in particular parsimony (see below). Other related methods such as neighbor-joining and maximum likelihood have been embraced by a subset of workers, but for various reasons are still not as widely used as parsimony. Thus, the discussion here will focus primarily on parsimony.

Analytical Methods

Phenetic Methods

Phenetics had its basis in the statistical literature that developed out of the “New Synthesis” and came to fruition with the advent of large and accessible computers in the late 1950s

and early 1960s. The various methods of phenetic analysis are too many to enumerate here but generally can be classified into methods that produce treelike diagrams (clustering) and methods that produce scatter diagrams on two or more axes (ordination). Phenetic methods do share the premise that all similarities, whether derived or primitive, should be used equally in an analysis. It is debatable as to whether the original proponents of phenetic methods actually intended the results of such analyses to be interpreted as phylogenies, but cluster methods produce treelike diagrams that were often directly interpreted as phylogenetic trees. Various justifications for phenetic methods have been proposed, and indeed, the methods as well as the theoretical underpinnings are eclectic. It became apparent in the 1970s and early 1980s that phenetic methods were not defensible as methods for recovering phylogenetic history, and parsimony analysis became the method of choice for most systematists interested in reconstructing patterns of divergence. Those interested in these debates can find entry into the literature by examining almost any issue of the journal *Systematic Zoology* from ca. 1970 to 1985. By the 1990s, phenetic methods had become rarely used except in particular subspecific and populational studies, and need not be considered further here.

Phylogenetic Methods

From the standpoint of methods of analysis, there is little to be gained by separating phylogenetics from cladistics although it should be noted that cladistics is the broader of the two. Cladistics is derived from the Greek term *clado* for “branch” and was coined by opponents of such methods to refer to those who were more interested in the pattern of divergence than in the process and degree of divergence. Originally the term cladistics was mostly applied to parsimony analysis (and some related methods that have fallen out of favor) but at the present time cladistics might be more broadly interpreted to include at least two other methods, neighbor-joining and maximum likelihood. However, as with all such terminology, there are differences of opinion, and some workers would rather restrict the term cladistics to parsimony-based methods only. For the purposes of this discussion, we will use the term in the broader sense. Any method that results in a (non-reticulate) tree diagram that is interpreted as representing the evolutionary history and relationships of taxa can be considered phylogenetic. Because of problems in interpreting most phenetic diagrams as phylogenies, those methods cannot be considered phylogenetic.

Parsimony

Parsimony analysis remains the method of choice for analysis of character data by most morphological systematists, and perhaps still even for molecular systematists. Modern parsimony analyses utilize matrices of either molecular or morphological data, or a combination of the two, to produce cladograms. Although Hennig did not propose parsimony analysis as we now implement it, his works provided the basis for the mathematical and theoretical underpinnings of parsimony analysis that were largely developed by Farris and others from 1969 to 1981 in a series of papers published in *Systematic*

Zoology and elsewhere. Parsimony is derived from Occam’s razor—the idea that the simplest explanation is always preferable. Parsimony analyses (when successful) result in cladograms (branching diagrams) that have the fewest number of steps (character transformations) when characters are optimally mapped onto the diagrams. Such trees are usually more or less directly interpreted as phylogenies, and character steps on these trees represent the minimum possible number of evolutionary changes to explain the distribution of the character. Such an interpretation does not require the assumption that evolution itself is parsimonious; indeed, most such trees based on real data have multiple origins for many, if not most, characters in the matrix. Parsimony simply eliminates the need for ad hoc explanations for multiple character origins by reducing them to the minimum possible number.

Parsimony Analyses

One major difficulty in parsimony analyses (and to an even greater degree in maximum likelihood) is the computational difficulty in finding most parsimonious solutions. There currently exist no methods for directly calculating most parsimonious trees. Because of this, the problem is directly related to the number of possible trees to be examined and is considered to be NP-complete. Because there is no direct way to calculate shortest trees, brute force methods that examine many possible trees must be used. These methods are generally implemented by “branch swapping” on a starting tree and examining the length of each new tree generated by moving branches to different positions on the tree. For very small data sets (< 15 taxa), it is possible to examine all possible trees and be certain that one has collected all of the most parsimonious trees. For slightly larger data sets (possibly up to 30 taxa, depending on the quality of data), it is possible to use a “branch and bound” algorithm that reduces the number of trees examined but still guarantees that all shortest trees are found. However, for the vast majority of analyses, more than 30 taxa, and in recent analyses, as many as several hundred taxa (or “terminals”), are included. It is important to note here that the number of characters (e.g., the length of a DNA sequence) only affects computation in a roughly linear manner, while computation time is affected logarithmically as the number of taxa increases. With larger analyses, branch swapping is used under various “quick” strategies to find locally optimal trees and these trees are then used as starting points for additional searches. Recent advances in search strategies have resulted in programs that can easily analyze data sets of several hundred taxa with a very high confidence that shortest trees have been found (see Goloboff, 1999). Currently, for matrices larger than 1000 taxa, quick estimation methods such as the jackknife are used instead of directly searching for shortest trees.

Homology

The term homology, like the term monophyly, is used in various ways in the systematic literature. However, most recent workers accept the term to mean a shared similarity that is due to (explainable by) common descent. Thus, any similarity that is not explained by common ancestry is not homology. Characters that are initially thought to be homologous but are found by analysis to be nonhomologous are termed homoplasious. Homoplasy is best considered as error in homology

assessment, which can be explained by parallelism, convergence, or other more complex processes such as hybridization and retained polymorphism. Homologous characters by definition are evidence of relationship. One theoretical basis for cladistic analysis using parsimony is that parsimony maximizes the homology statements presented in the data matrix. Thus, when we score two terminals (taxa, species, etc.) as having the same state for a character, we are asserting a hypothesis of homology (the “primary” homology of some workers). Parsimony then resolves conflict among such statements by picking the tree (cladogram) that maximizes the number of correct homology assessments (or minimizes the number of incorrect assessments). In so doing, it minimizes the number of ad hoc explanations that are necessary to explain similarities that appear to be homologous at first, but are not based upon the most parsimonious tree. Farris and others have demonstrated that the shortest trees maximize explanatory power as well as information content of a classification and are therefore preferable even outside of an evolutionary context. It is important to note that parsimony does not assume that evolution is parsimonious, only that parallelism and convergence are not correlated in such a manner as to be misleading. Given randomly distributed parallel and convergent false homologies, with enough “true” homologies parsimony will resolve the correct tree (the tree that most accurately reflects phylogenetic history). This assertion has been challenged recently by proponents of maximum likelihood, but this controversy remains unresolved at this time and it appears that all methods (parsimony and maximum likelihood included) fail under certain circumstances.

Neighbor-Joining (NJ)

Neighbor-joining is a method that is arguably cladistic and is favored by many molecular biologists because it is rapid and generally (at least as commonly implemented) results in a single tree. The basic algorithm of NJ is similar to the Distance Wagner method of Farris and constructs a tree by calculating distances among terminals and adding terminals in such a way as to minimize overall distance. While NJ is an expedient method for quickly obtaining an estimate of the most parsimonious tree, there seems to be no justification for preferring an NJ tree over a shorter tree obtained by parsimony analysis.

Maximum Likelihood (ML)

Maximum likelihood as a method of analysis is popular among many molecular biologists, particularly those who are more interested in models of evolution than in the actual phylogenetic pattern of taxon relationships. ML requires an explicit model of character transformation, with associated probabilities for each possible transformation from one state to another. Trees are searched in a manner similar to methods used in parsimony (e.g., branch swapping) but each tree is evaluated not by overall length, but instead by a measure of compound probability. Those trees with the highest compound probabilities (maximum likelihood) of character distribution are selected as best. Within certain theoretical frameworks, parsimony can be viewed as a particular form of maximum likelihood with reduced assumptions and infinite parameters. Under such circumstances, parsimony analyses and maximum likelihood analyses will give the same results.

Under most circumstances, maximum likelihood and parsimony analyses of the same data sets have provided very similar results. However, at the present time maximum likelihood is not feasible for larger data sets due to massive computation times (at least with today’s hardware and software). The computational problems are unlikely to be resolved by the mere improvement of hardware and will require advances in software that are probably not possible with current engineering capabilities in this field. However, it is possible that recent advances in algorithms for parsimony searches can be incorporated into maximum likelihood programs with similar relative levels of improvement. Because of the additional complexities of ML, even with such improvements, the ability to perform maximum likelihood analyses on the ever-larger data sets being produced with molecular techniques will lag behind parsimony for the foreseeable future.

Measures of Support

The Bootstrap

Many workers wish to place some measure of statistical confidence on the phylogenetic trees that they construct. Because of theoretical issues, it is preferable to refer to such statistical measures as support values as opposed to confidence intervals. The most widely used support measure in recent literature is the bootstrap. The bootstrap is calculated by permuting the original data set numerous times by sampling characters with replacement and recalculating the most parsimonious trees for each permuted data set. Usually, from 100 to 1000 separate permuted data sets are analyzed, and support for a particular clade can be evaluated as the number of separate replicates in which that clade occurs in the most parsimonious solutions. Thus, if a group is found in parsimony analysis of 90 of 100 permuted data sets, its bootstrap value would be 90. Theoretical issues surrounding the bootstrap include the assumptions about character distribution and sampling and the exact interpretation of the bootstrap values that are obtained for each branch in the tree. Because the relationship between the bootstrap values and the underlying “true tree” is not apparent, many workers prefer to view bootstrap values as an assessment of the strength of signal within a particular data set, and not as a statistical measure of confidence except in a very restricted sense. This has resulted in development of an alternative terminology, under which bootstrap (and jackknife) values are referred to as “measures of support.”

The Jackknife

The jackknife is closely related to the bootstrap and is performed also by permuting the data set and counting the occurrence of groups (clades) among replicates. The jackknife differs from the bootstrap in that instead of resampling characters, characters are removed at a set level of probability—the probability of removal usually set to be the same as the probability of not being sampled in a bootstrap. The jackknife has some theoretical advantages over the bootstrap and is generally faster to calculate because of very fast software

that is available. The jackknife has been used recently as the sole analytical method for some very large molecular data sets (e.g., Kallersjö's analysis of an rbcL data set for green plants with more than 2000 taxa). Indeed, some proponents of the jackknife have suggested its exclusive use in lieu of more intensive parsimony analyses, under the view that only well-supported clades need be recovered. This is not an abandonment of parsimony, but rather a rejection of poorly supported conclusions under a parsimony optimality criterion.

Bremer Support

Another measure of support commonly used in conjunction with parsimony analyses is Bremer support, sometimes incorrectly termed the "decay index." Bremer support is measured by collecting suboptimal trees (trees of longer length than the shortest) and determining which groups are present. If, for example, a clade is present in shortest trees and all trees up to 2 steps longer, but is not present in all trees 3 steps longer, the Bremer support value for that group is 3 steps. While Bremer support is appealing because it utilizes parsimony directly, it is difficult to compare Bremer support values among different data sets. In general, the bootstrap and jackknife have been preferred in recent years as measures of support, and especially for large data sets, the former two are much easier to calculate than Bremer support.

Data Sources

Phylogenetic analyses have evolved from being entirely or largely based on morphological data to being more and more based on molecular data, in particular DNA sequence data. There are both theoretical and practical reasons for this shift. First, many believe that molecular data are more objective and that character definition and scoring of morphological characters is both more subjective and subject to error. Because the expense of sequencing DNA has dropped dramatically, it is arguable now that it is actually more cost-effective to extract and sequence DNA than to spend large amounts of time tediously collecting morphological data. One problematic aspect of DNA sequence data is the lack of such data for fossil taxa. Fossil taxa, when available and when well preserved, can often be included in morphological cladistic analyses and may provide additional insight into patterns of relationship. Occasionally, such fossils even may have dramatic effects on the position of particular taxa. A major caveat of the inclusion of fossil taxa in cladistic analyses is the large amount of missing or incomplete data for fossils, especially in "soft" features that do not preserve well. Terminals with large amounts of missing data have the potential to "move" on the most parsimonious trees, resulting in many equally parsimonious solutions and in essence "deresolving" the tree. Such taxa that move because of ambiguity in data are often referred to as "wildcards" because of the propensity for them to match multiple terminals in the analysis. In general, it is best not to include such fossils when there is evidence that they are not contributing relevant information to the analysis but instead are reducing the precision of the results.

In the early 1990s a debate developed about the best way to treat disparate data sets, such as different gene sequences, or gene sequences and morphology. One side suggested that data sets should be analyzed separately unless it could be shown that they were congruent, while the other proposed that data sets should be combined as the best method to resolve such incongruence. Currently, it appears as though the latter position is more popular, since most multigene studies combine data sets in a simultaneous analysis regardless of whether tests indicate congruence.

The availability of vast quantities of molecular data across broad groups of taxa holds the promise of providing more or less complete large-scale phylogenies in the near future. Theoretically, larger analyses with more taxa should provide better estimates of relationship that are less sensitive to the addition of new data. Using parsimony jackknifing, [Lipscomb and co-workers \(1998\)](#) analyzed all of the eukaryotes in the Ribosomal Database Project (480 eukaryotes, 15 prokaryotes as outgroups). This analysis confirmed previous morphological and molecular studies that indicated that the protista and fungi were not monophyletic. However, this analysis showed that several of the startling and "new" findings of molecular systematics were probably the result of analysis of small data sets. In particular, there was no evidence for placing *Giardia* and its relatives as the most primitive eukaryotes nor any clear indication that the Dinoflagellates were sister to the Apicomplexa.

Phylogenetic Interpretation

One aspect of phylogeny and phylogenetic reconstruction that often presents difficulty is the interpretation of phylogenetic trees as evolutionary diagrams. Imprecision in both terminology and concepts has resulted in interpretations that are often inaccurate and unsupported. One of the most common mistakes in interpreting cladograms (or phylogenies) is the tendency to view the trees as providing a linear sequence of events, with a "first branch" that bears a more primitive group, followed by a "second branch," etc. Such terminology generally confounds group size with time of origin, usually placing the smaller extant group of two concordant groups at the "base" of the tree. Thus, recent molecular analyses of the angiosperms have often been characterized as placing *Amborella* at the base or as the first branch of the angiosperms (see [Figure 1](#)). However, the correct way to view such diagrams is in a *dichotomous* linear time scale, with each successive dichotomy younger than the preceding. In [Figure 1](#), time can be viewed as proceeding from left to right. *Amborella* is not itself the first branch anymore than the angiosperms minus *Amborella* is the first branch—the first two branches of the angiosperm tree bear a single species, *Amborella*, on one side and a few hundred thousand species (the remainder of angiosperms) on the other side. In terms of primitive or derived features, *Amborella* might be more derived than numerous persisting species on the other, larger branch of angiosperms and should not be viewed simply as the "most primitive" angiosperm. For instance, any one of several taxa near the base of the diagram (e.g., *Nymphaea*) might be more similar to the primitive angiosperm than is *Amborella*.

Figure 1 Reduced phylogenetic tree based on a recent large-scale molecular parsimony analysis of seed plant relationships. The results suggest that Amborella is the remaining extant sister taxon of the remainder of angiosperms; note that this tree does not indicate that Amborella is “the most primitive” flowering plant. See text for discussion.

However, Amborella might be considered to be the “most unique” angiosperm since it is the sole representative of one of the two basal clades (based on extant species alone) of angiosperms, and in that sense is the equivalent of the remainder of angiosperms. This simple and direct view of branching patterns in a phylogeny is not only the correct way to interpret phylogenetic diagrams, but it also provides the basic concept of phylogenetic diversity, or the measure of phylogenetic uniqueness, that is outlined below.

Another common mistake in dealing with phylogenies is the interpretation of polytomies, or multifurcations in cladograms, as indicating rapid radiation from a single ancestral plexus (see **Figure 2**). Often, such patterns are referred to as “star phylogenies.” Although evolution may not always produce dichotomous divergences, it is not possible to positively identify multifurcations as rapid divergences. Instead, such patterns may simply reflect a lack of sufficient data to resolve more completely bifurcating trees. In general, polytomies reflect a lack of conclusive evidence that is due to either character conflict or lack of data. Polytomies are best viewed simply as areas of the tree that need additional data to resolve, unless other independent data support a hypothesis of rapid divergence at the point of the polytomy.

Another frequently misunderstood aspect of phylogenetic analysis is the role of *a priori* character polarization. In the 1970s, many of the computer programs used to calculate phylogenetic trees required *a priori* character polarity (the assignment of “primitive” and derived states). However, strict parsimony analysis will produce the same topology regardless of the ultimate character polarity of the characters; in fact, parsimony computer programs do not consider character polarity during tree searches. Beginning in the late 1970s, it became apparent that the correct method for rooting trees was to select one or more outgroups that were included in the analysis, and the resulting trees rooted between the outgroup(s) and the ingroup. Although the best choices for outgroup taxa are those that are closely related to the ingroup, virtually any

Figure 2 A portion of a phylogenetic tree based on a consensus tree from a parsimony analysis of a selected group of families of flowering plants. Note the large polytomy, or “star phylogeny” as such patterns are sometimes called. Such structures do not necessarily indicate rapid divergence from a common ancestor, but instead reflect lack of sufficient evidence, or conflicting evidence, regarding relationships. The graphic tree style was selected to more clearly indicate polytomies.

taxa not part of the ingroup may be used. However, the more distant the outgroups, the less accurate the rooting is likely to be, and particularly with molecular data, if the outgroups are too far removed, virtually random patterns of rooting may emerge. Character polarity becomes a matter of reading character distributions from the resulting trees when the outgroup method is employed, not an *a priori* exercise. Not only is this far easier than attempting to assign polarities to characters directly, but it reduces a major source of subjectivity in the analysis of data. Maximum likelihood models that allow equal probability for changes in any direction are also calculated independent of *a priori* rooting, but any models that have asymmetric models of character change are sensitive to a choice of a root, or starting point.

Phylogeny and Classification

The issue of how to classify taxa into formal named systems may seem trivial to some biologists, but it has a profound impact on the way that we think about living things, and therefore does have an impact on the design and implementation of many biological studies. Statements such as “reptiles are cold blooded” or “reptiles have scales” or “the dinosaurs went extinct in the late Cretaceous” all have different interpretations depending on the classification in use. Characterization of paraphyletic groups on the basis of widespread and notable characters (e.g., the scales of “reptiles” or the naked seeds of “gymnosperms”) may provide useful means of communicating, but in formal classifications paraphyletic groups often provide misleading implications about relationship. Thus, if we include crocodiles in the group reptiles, we might

guess that crocodiles are more closely related to lizards than to birds; this in fact is not the case, based on several lines of evidence when analyzed cladistically that reveal that crocodiles are more closely related to birds than to other “reptiles”—in other words, crocodiles and birds form a monophyletic group that excludes other reptiles and mammals (see [Figure 3](#)). The advantage of a phylogenetic classification lies in the information content; if we know that a classification adheres strictly to the rule that all named groups are monophyletic, then all members of the group will be more closely related to each other than to any taxa *not* included in the group. Traditional groups such as “reptiles” (or formally, Reptilia) do not meet such criteria, and unfortunately it is impossible to know from such a nonphylogenetic classification that crocodiles (when placed within the “reptiles”) are more closely related to birds than to other “reptiles.” This observation at once supports both the need to abandon paraphyletic groups in formal classifications, and in doing so, to adopt a system of classification that is based consistently on phylogeny—with named groups always corresponding to groups based on available evidence that are believed to be monophyletic.

Much of the difficulty that some systematists and many outside of systematics have with the abandonment of paraphyletic groups comes from the intuitive nature of such groups and their often easy characterization (e.g., reptiles are scaly, air-breathing, cold-blooded vertebrates that lay eggs). A classification that recognizes paraphyletic groups must do so based on primitive (plesiomorphic) features, as in the example just provided. The difficulty, and the arbitrary factor in such classifications, comes not in what to include in a paraphyletic group but instead in what to exclude. Because there is no objective way to determine what groups are significant enough to be excluded, the final decision is left to the authority, and in the strictest sense of the term, such classifications are authoritarian—and each authority may recognize different groups. Thus, removal of the birds from the group “reptiles” is based on a particular viewpoint about the

importance of the characters (e.g., feathers) that the groups possess. However, another authority might just as easily argue to remove snakes (they lost those encumbering limbs) or turtles (the ultimate innovation in defensive armor). Decisions to exclude (and thereby elevate) groups such as birds are ultimately based on a view on the importance of particular characters, and such classifications do not accurately convey information about relatedness. Unfortunately, because paraphyletic classifications are based on arbitrary assignments of significance to characters, they are not even useful in the prediction of innovation or levels of anagenetic change (there is no measure of the amount of change involved in the removal of concordant groups, only its significance). The realization that paraphyletic classifications are at their base arbitrary is the first step toward the acceptance of the need for classifications based solely on monophyly.

Ranks and Priority

The need for a useful classification to be based on phylogeny has been confounded in recent years with other aspects of classification, such as ranking and the priority of names. Recently, a movement has emerged that has been self-proclaimed as “Phylogenetic Systematics,” which putatively embodies the ideals of Hennig and requires strict translation of phylogenies into named classifications. However, the need for maintaining only monophyletic named groups has been intertwined with other proposals, such as the abandonment of ranks, and proclamations that the existing Linnean system is incapable of accommodating a truly hierarchic system. Of course, the Linnean system is a strictly hierarchic system, and the claims that it must be abandoned are both premature and poorly reasoned. Unfortunately, many outside of this controversy have been misled to believe that the new proposals will provide greater stability in names, which is untrue. Stability in names in any phylogenetic system will come with stability in the underlying phylogenies on which the system of classification is based, and we are on the verge of achieving such stability with the vast quantities of molecular data and improved analytical algorithms that are becoming available.

Applications of Phylogeny

General Evolutionary Context

In recent years, phylogeny has become an important aspect of many evolutionary and ecological studies. Phylogenetic studies focus on the pattern of history, but provide the foundation for both generalizations and specific conclusions about processes of evolution and diversification. Generalizations about evolutionary process based on phylogenetic trees are more predictive because phylogenetic trees provide information about character distributions as well as relationship. Phylogenies also provide the ultimate test of particular ideas or theories about the course of evolution. By mapping character distributions in the most parsimonious possible manner on a well-supported phylogeny, it is possible to understand whether characters of interest have evolved once or more than once and whether particular characters are correlated in a

Figure 3 A phylogenetic representation of relationships among major groups of vertebrates, based on several published studies of morphological and molecular data. Note that crocodilians are more closely related to birds than to other “reptiles.”

historical sense. Attempts in the past to accomplish these goals were often based on paraphyletic classifications that were misleading or based merely on ranked classifications with unknown or unstated bases. Without a clear understanding of phylogenetic pattern, these studies often miscounted the number of times evolutionary steps occurred within and among taxa and came to incorrect conclusions about character evolution. Precise phylogenies now provide a means to improve such studies.

Adaptation

Phylogenetic trees have become a standard tool in the study of adaptation, and such uses are often referred to as the “comparative method.” First, it is necessary to establish that a particular “adaptation” is distributed as an apomorphy within the group in question and then, if there are multiple origins, to determine if these origins are correlated with other characters and/or environmental variables. While numerous statistical approaches have been suggested for such studies, they all assume that multiple independent origins of characters correlated with environmental or historical factors are evidence of adaptation. Indeed, some workers maintain that it is only possible to discuss adaptation in a historical context, i.e., based on explicit phylogenetic trees. Undoubtedly continued work in these areas will result in improved statistical tests for adaptation based on character distributions on phylogenetic trees.

Vicariance Biogeography

Phylogenetics has also become the main tool for biogeographic studies, and indeed the field of biogeography is now almost synonymous with vicariance biogeography. Vicariance biogeography is rich in theory and a thorough explication is beyond the scope of this article. The basic premise is that historical patterns of land connection and movement are recoverable through finding repeated patterns among the phylogenies of various plant and animal groups. Repeated patterns of clade distribution suggest a common history that is interpretable as supporting wider continuous distributions in the past. A well-known example of a broad vicariant pattern of distribution is found in the plant genus *Nothofagus* (Nothofagaceae) in the Southern Hemisphere, with species distributed in South America, New Guinea, Australia, New Caledonia, and New Zealand and fossils known from Antarctica. Similar patterns in other plants (e.g., Proteaceae) and animals (e.g., ratite birds) can be evaluated in a phylogenetic context to provide evidence of interchange among different “areas of endemism” and develop an “area cladogram” that presents a pattern of relationship among the land areas. These patterns can then be interpreted in the context of plate tectonics as indicators of historical fission of land masses and subsequent plate movements.

Phylogeny and Biodiversity: Phylogenetic Diversity

Phylogenies also provide a framework for alternative ways of looking at biodiversity. Most measures of biodiversity

use species richness, either in a geographic (either broad or local) or ecologic sense. Other views of diversity may focus on the nature and breadth of adaptation. Such measures unfortunately require a subjective view of the importance of particular adaptations—e.g., the birds might be considered “diverse” because they include so many adaptations for use of the bill. However, phylogeny provides another perspective on biodiversity that allows an objective way to compare uniqueness and diversity of taxa. Although various specific measures of phylogenetic diversity have been proposed, most share a basic approach by which phylogenetic trees are used to evaluate species richness in concordant groups. It means little to say that “orchids are highly speciose” or “monotremes are species depauperate” unless we have some idea as to the relationships of the two groups being compared. Phylogenetic pattern provides the basis for such comparisons.

Currently, the use of phylogenetic diversity measures is largely limited to theoretical discussions and there have been few efforts to actually apply such measures to conservation. This is partly due to the relative paucity of high-quality phylogenies that are available across broad groups of taxa and partly because of a distinctly ecological bias in most studies of biodiversity. As molecular data sources provide better and more complete phylogenies for use by other workers, this is likely to change. It is probable that in the near future measures of phylogenetic diversity will become standard components, in combination with more traditional measures of ecologic uniqueness, species richness, and sensitivity, in the formulae that are used to evaluate conservation priorities for areas and endangered species.

Conclusions

An understanding of phylogeny is increasingly important as a basis for experimental design and for interpretation of results in a broad array of biological studies. New methods of analysis, improved computer hardware and software, and new and improved sources of data, most notably DNA sequences, have revolutionized our ability to construct phylogenetic trees. It is likely that our understanding of the origins and diversification of most major lineages of plants, animals, and microorganisms will improve dramatically over the next century, and we will arrive at a stable and robust reference system for all of life on earth.

Glossary

Community A group of coexisting species characterized by taxonomic composition and/or structural type, possessing repeatable associations of dominance, diversity, and trophic interaction.

Competition Interactions between two or more organisms for biotic or abiotic resources, resulting in decreased fitness of one or more of the participants.

Diversity A quantitative measure of the taxonomic or physiognomic composition of coexisting organisms at one of three scales: alpha (local diversity), beta (diversity change

between adjacent local sites), and gamma (regional diversity).

Niche An organism's biotic and abiotic resource requirements, collectively enabling the organism's trophic and behavioral role in the community.

Succession Changes within ecological time spans in the taxonomic or physiognomic composition of a specific community in response to biotic or abiotic perturbation.

Turnover Changes in the taxonomic and possibly physiognomic composition of a community over evolutionary timescales in response to environmental or evolutionary change.

Introduction

In the past few decades, questions about the creation, maintenance, and role of biological diversity have stimulated social, political, and scientific inquiry. However, the fundamental mechanisms responsible for biodiversity remain poorly understood. We review the patterns in contemporary and historical plant communities that we believe are critical to achieving a better understanding of the processes that regulate diversity. In doing so, we take an actualist (or pure uniformitarian) stance: We assume that the basic physical and biological processes that regulate diversity today are manifestations of natural "laws" that have been in operation throughout the existence of the earth.

Clearly, any realistic juxtaposition of the concepts derived from neo- and paleoecological studies requires a clear exposition of the limitations and evidence on which they rest. Paleo- and neontological research programs each bring different strengths to bear on the question of how biological diversity originates and is maintained. The greatest strength of neoecology is the ability to achieve fine resolution. Much of what is known about the ecological dynamics of plant and animal communities is based on detailed, short-term, small-scale, neontological studies. These studies emphasize the role of local processes such as succession, predation, competition, mutualism, abiotic stress, and a host of other ecological phenomena in the regulation of biodiversity. On the other hand, the paleontological research program tends to emphasize the influence of evolutionary and physical changes on the species composition of communities. Despite their different strengths, the two disciplines often reach similar or complementary conclusions. For example, both paleontology and neontology concur that community composition is highly variable over space and time (Ricklefs and Schluter, 1993;

Brown, 1995). Communities do not consist of a "tight-knit" assemblage of co-occurring species; instead, species respond individually to changing biotic and abiotic conditions.

Differences between the disciplines in the level of taxonomic, spatial, and temporal resolution have important consequences on how phenomena are defined and perceived. Within neontology, the definition of coexisting species can vary from very small sets to regional assemblages. In most cases, neo- and paleoecologists use the same vocabulary (e.g., community, taxonomic diversity, and stability), but the meanings of these words change as a function of the spatial and temporal scales used in the two fields. Despite these potential pitfalls, we believe that we can improve our knowledge of the important community processes by focusing on the complementary strengths of each discipline.

Brief Overview of the Evolution of Terrestrial Plants

The fossil record clearly shows that the number of plant species has increased over geological time (Figure 1; Niklas, 1997). The first land plants were diminutive, nonvascular, bryophyte-like organisms that inhabited the margins of the terrestrial landscape and provided resources and shelter to the first land-dwelling animals. These plants were restricted in their geographic coverage owing to their dependence on liquid water for vegetative survival and reproductive success (Batteman *et al.*, 1998).

The earliest vascular plants possessed better vegetative adaptations to life on land but were also tied to moist habitats for reproduction. They quickly diversified in morphological complexity, primarily during the Devonian, a period that saw the first plants with leaves, roots, lateral meristems, and an erect habit. These plants were larger than their nonvascular

Figure 1 Total number of species and species turnover. Number of vascular land plants and change in species number are plotted as a function of geological time. Data for vascular land plant species are segregated into three reproductive groups (pteridophytes, gymnosperms, and angiosperms). Solid curved line denotes ordinary least squares regression curve for the cumulative data. Change in species number (turnover) is computed on the basis of the appearance and disappearance of species in each geological stage. 1, Origin of seed, origin of arborescent habit; 2, diverse lowland swamp communities, high atmospheric oxygen; 3, sequential decline in diversity and occurrence of pteridophyte-dominated communities, coalescence of Pangea; 4, gymnosperm-dominated communities common, Pangea slowly breaks up; 5, angiosperms first appear in the fossil record and begin to spread, becoming the dominant floristic element; 6, Cretaceous–Tertiary boundary, angiosperms diversify and become the dominant vegetational element, including closed forest communities; 7, Eocene–Oligocene climatic shift leads to dramatic Earth cooling; 8, herbaceous angiosperm communities radiate, including grasslands; 9, taiga and tundra biomes fully developed.

progenitors. By Late Devonian times, vascular plants evolved the capacity for secondary growth and with it the ability to form forests. These changes increased the complexity of the physical structure of plants and the diversity of resources available within terrestrial communities, creating opportunities that were subsequently exploited by the evolution of plants with vining, epiphytic, and understory lifestyles. Initial stages of the seed habit also evolved by the Late Devonian, allowing new ecological solutions within the swamp community and laying the groundwork for the subsequent establishment of communities in drier habitats in the Carboniferous. The basic physiognomies of modern plant communities were well established approximately 300 million years ago.

From the late Carboniferous through the early Mesozoic, gradual environmental changes associated with the formation of Pangea resulted in extinctions of lowland taxa and their replacement by increasingly drought-tolerant taxa migrating

from more mesic sites. This established an early mid-Mesozoic flora dominated by a host of seed-bearing clades collectively known as the gymnosperms. Pteridophytes survived but were a secondary element of Mesozoic vegetation.

Angiosperms became an important ecological element approximately 115 million years ago, in the Early Cretaceous. They initially evolved as disturbance-tolerant herbaceous and shrubby plants occupying early successional environments, but they quickly radiated. By the Late Cretaceous, angiosperms started to appear as forest trees in increasingly more stable sites, and they were the most diverse terrestrial plant clade. However, it is not clear if they formed the dominant vegetation at this time. By the early Tertiary, angiosperms were represented by many living families and genera forming closed-canopy forests in temperate and tropical climates, and they dominated Earth's vegetation. Cooling and drying climates in the later Tertiary resulted in the diversification of mid-continental grassland communities and the rearrangement of

individual distribution patterns that created the biomes of the present. The rise of angiosperms established the full complement of structural and reproductive features (e.g., complex canopies, diverse life history, and reproductive strategies) observed today as well as creating the most diverse terrestrial communities in Earth's history. In their radiation, angiosperms did not displace equally diverse nonangiospermous seed plant communities. Rather, angiosperms both inserted themselves into existing communities and created totally new communities, often creating new opportunities for existing clades. The result has been the most speciose plant communities yet seen on Earth (Figure 1).

Niche Diversification and Competition

Understanding the evolution of plants in terms of niches provides the basis by which one can begin to assess the evolution of diversity within plant communities. The concept of the niche is useful because it provides a framework linking individual traits, such as morphology, physiology, and behavior, with their interactions with the biotic and abiotic environment. These features in turn influence population level traits such as growth, abundance, and distribution (Brown, 1995).

Both ecological theory and empirical evidence stress that competition is one of the important forces driving niche diversification and thus community diversity (Knoll (1986) as cited in Rosenzweig, 1995). The increase in plant species diversity through time is paralleled by evolutionary shifts in resource requirements, body size, allocation strategies, and life history traits suggestive of niche diversification and thus of the action of competition. Indeed, the degree of difference or similarity that is required for coexistence has not been quantified, and it has been hypothesized that two or more plant species with very similar resource requirements can coexist indefinitely in the same community as long as their reproductive units (e.g., spores, seeds, or fruits) are dispersed randomly such that adults do not consistently grow in close proximity (Hubbell and Foster as cited in Ricklefs and Schluter, 1993; Brown, 1995; Rosenzweig, 1995; Crawley, 1997).

Competition, however, is difficult to effectively demonstrate in the fossil record. At large temporal scales, such as those encountered in the fossil record, the evidence suggests that competition may be supplanted by other features such as shifts in the physical environment (Niklas *et al.* (1985) as cited in Ricklefs and Schluter, 1993). The shift from a Pteridophyte-dominated late Paleozoic flora to a seed plant-dominated Mesozoic flora appears to have been caused by global climate change that selected against the reproductive modes of many pteridophyte lineages, resulting in extinctions in existing lowland communities. Opportunistically, seed plants migrated in from more mesic sites to replace the lowland pteridophytes. Similarly, gymnosperm diversity was not drastically affected by the evolutionary appearance and subsequent diversification of angiosperms, despite the observation that contemporary gymnosperms are ecologically displaced by the more rapid vegetative growth and reproduction of flowering plant species (Niklas *et al.* (1985) as cited in Ricklefs and Schluter, 1993).

The evidence suggests that although niche diversification is driven largely by competition, major changes in community composition at evolutionary timescales have been initiated by larger scale physical changes.

Body Size and Plant Form

Body size influences nearly all the characteristics of organisms and ultimately the composition of the communities they inhabit (Brown, 1995). The ecological and evolutionary ramifications of body size appear to have been an important basis for differentiation in vascular plants. Neocological observations indicate that mass-specific metabolism, age to reproductive maturity, relative growth rate, and population density are all inversely correlated with body size (Niklas, 1997; Enquist *et al.*, 1999). Thus, although the total resource needs of larger individuals increase, their use per-unit-volume or per-unit-mass decreases. Body size also affects biological timing. For example, larger species have longer life spans and longer times until reproduction than do smaller species. Increases in size allow species to partition resources over time: Small species tend to be more sensitive to short-term environmental variation, whereas large species apparently cue to longer term fluctuations.

Individual clades within pteridophytes, gymnosperms, and angiosperms often display Cope's rule: Derived taxa tend to become larger. An increase in size confers a competitive advantage in the struggle for the resources, such as light and nutrients, that are necessary for growth and reproduction (Harper (1977) as cited in Crawley, 1997). Paleoeological data indicate that Cope's rule may also reflect the tendency for new clades to make their evolutionary debut in disturbed habitats (DiMichele *et al.*, 1987; Niklas *et al.* (1985) as cited in Ricklefs and Schluter, 1993). Such species often possess a small body size and its associated rapid vegetative growth and onset of sexual maturity (i.e., the classic r-selected species). Conversely, larger species within many plant clades appear to occupy more ecologically stable habitats.

Over long time spans there may be selection against larger sizes. Larger species tend to be more prone to extinction during periods of environmental change than their smaller counterparts (Bakker (1977), Stanley (1979), and Tiffney and Niklas (1985) as cited in Niklas, 1997; Brown, 1995). Presumably this is because larger species take more time to reach reproductive maturity, tend to produce fewer progeny per reproductive cycle, and have lower population densities per unit area. This suggests that evolutionary processes operating on microevolutionary and macroevolutionary timescales may have conflicting outcomes. Under the limitations of physical and biological constraints, organisms benefit from competitive advantage by becoming larger until an unpredictable environmental change forces them to extinction.

A plant's form, or shape, is as important as its size in partitioning ecological opportunities. Many aspects of plant form and architecture can be interpreted as the result of natural selection acting to optimize biomechanical stability and the ability to procure resources from the environment while minimizing hydrodynamic costs of resource transport (Niklas

and Kerchner (1984) as cited in Niklas, 1997; West *et al.* (1997, 1999) as cited in Enquist *et al.*, 1999). Only a relatively small number of “plant designs” appear to be functionally viable over the range of sizes within which vascular plants operate. It can be shown via mathematical modeling and computer simulation that most of these viable options have been exploited (Niklas and Kerchner (1984) as cited in Niklas, 1997) and that the evolution of plant size has been strongly limited by biomechanical constraints (Niklas, 1997; Bateman *et al.*, 1998). In summary, although selection has apparently operated to increase plant size within clades, physical and biomechanical constraints have restricted maximum size (Figure 2).

Allocation and Reproductive Strategies

Biomechanical limitations restrict niche partitioning involving body form. However, plants with different forms may vary the allocation or timing of energetic output, thus increasing the potential for coexistence. Separate species attain their “adult” size at different times by altering growth rates. Unless the total amount of energy available to the individual plant changes, such changes in growth rates must be accompanied by a trade-off in other activities requiring energy. For some species, changes in growth rate are compensated for by changes in wood density: Fast-growing arborescent species generally produce wood of a much lower density than do slower growing species (e.g., balsa versus mahogany; Enquist *et al.*, 1999). This has obvious implications for relative mechanical stability, susceptibility to disease, and species longevity. Similarly, an energetic trade-off exists with regard to the ability to tolerate herbivory, parasitism, and disease (Crawley, 1997). By investing energy in the formation of secondary chemicals, plants can often avoid enemies, albeit at the cost of slower growth and delayed sexual maturity.

Perhaps the area in which different allocation strategies have the strongest effect is within reproduction. Plants can alter both the proportion of resources used in reproduction and the amount of resources allocated to individual disseminules. Such adaptations are often linked to community structure. Large seeds, for example, tend to occur in forest communities, whereas smaller seeds are more common in open or disturbed habitats (Crawley, 1997). Variation in reproductive strategy provides plants with additional ways to partition environmental opportunities and coexist.

The fossil record suggests that reproductive adaptations have permitted the ecological exploration of previously poorly colonized terrestrial environments, starting with the invasion of land, the evolution of the seed, and finally the suite of adaptations involved in the origin of angiosperms (Niklas, 1997). Early land plants possessed pteridophytic reproduction, requiring freestanding water. With evolution of advanced forms of gymnospermy, this dependence was lost, but at the cost of vegetative reproduction, because all nonangiospermous seed-bearing plants were apparently either shrubs or trees capable of only limited vegetative reproduction.

The evolution of the seed habit, specialized dispersal mechanisms, and the capacity for seed dormancy opened up many new habitats in the late Paleozoic and Mesozoic. Together, specialized dispersal and seed dormancy permitted further niche diversification within plant communities. The morphology of dispersal units through the Late Cretaceous suggests that seed dispersal was primarily abiotic. The evolution of large seeds in many angiosperm lineages during the early Cenozoic indicates the increasing importance of animal dispersal. Additionally, the ability of seeds to remain dormant has many important ecological implications, potentially enhancing local coexistence by enabling potential competitors to partition niches in time and space. Furthermore, dormancy enables plants to “wait” until specific environmental

Figure 2 Record stem diameters. Largest reported stem diameters plotted as a function of geological time. Data from Niklas KJ (1997) *The Evolutionary Biology of Plants*. Chicago: Univ. of Chicago Press.

conditions are present, such as a rare rain in the desert or a high nutrient defecation following passage through an animal's digestive tract. Dormancy holds the potential for greater dispersal distances and the formation of seed banks, enhancing the geographic ranges of species and their capacity to deal with potentially protracted inclement environmental conditions. Dormancy, however, may also increase the probability of seed predation.

It is only with the angiosperms that asexual vegetative reproduction and the seed habit are found to commonly co-occur within an individual with either an herbaceous or woody growth habit. The possession of rapid sexual life cycles, the potential for an herbaceous habit, and in many cases the potential for vegetative reproduction predisposed angiosperms to outdiversify and potentially outcompete other lineages in multiple ways in response to environmental changes especially in the Cenozoic. These traits allowed for further invasion of new habitats, such as desert and arctic/alpine environments.

Plants and Climate: Physiognomy and Physiology

The patterns of plant diversity and distribution are influenced by climate. Most biomes show a remarkable degree of convergence in plant architectures, size structure, and physiology, despite drastically different biogeographic and evolutionary histories of their component taxa (Leigh (1975) and Mooney (1977) as cited in Brown, 1995; Milewski (1983) as cited in Ricklefs and Schluter, 1993). Many of the physiognomic features associated with plants found in communities within each of these biomes, such as the relative proportion of compound and simple leaves, root to shoot ratios, plant heights, leaf cuticle thickness, and leaf indument, all show consistent trends with variation in temperature, precipitation, humidity, and rainfall (Crawley, 1997; Raunkiaer (1934) as cited in Crawley, 1997; Wolfe (1978, 1979) as cited in Ricklefs and Schluter, 1993). Indeed, because of the tight association between vegetative physiognomy and climate, physiognomy is often used as a proxy for reconstructing past climates.

The tight link between climate and physiognomy is due mainly to physiological and stoichiometric tradeoffs (Crawley, 1997). One of the most important is the trade-off between water and carbon balance. In order to assimilate atmospheric CO₂, plants must be able to exchange gasses through their stomata, but open stomata cause water loss via transpiration. In many terrestrial environments water stress can limit rates of production by reducing photosynthesis. The evolutionary history of terrestrial plants is marked by the evolution of adaptations that enhance the ability to increase productivity in the face of water stress. The initial radiation of vascular plants was most likely due to the evolution of a cuticle pierced by stomata whose aperture could be regulated (Niklas, 1997). These adaptations were honed through the subsequent evolution of sunken stomata, leaf pubescence, physiologically dormancy, and the ability to mechanically position leaves in response to environmental change. Such morphological adaptations allowed for the colonization of more seasonal environments (Hutton *et al.* (1998) as cited in Bateman *et al.*, 1998).

Although it appears that changes in morphology allowed for the continued exploitation of new resources and habitats, physiological processes appear to be highly conserved over geologic time (Raven (1995) as cited in Bateman *et al.*, 1998). However, interpreting these features is difficult from fossils because the process of preservation alters chemical fossils. When physiological processes are mirrored in morphology, we infer physiological evolution. For example, changes in the density of leaf-borne stomata appear to correlate with geochemically predicted changes in atmospheric CO₂ content, at least back through the Mesozoic. Other morphological features suggest that basic plant physiology has changed little in 400 million years. C₃ photosynthesis appears the norm; CAM photosynthesis may have evolved by the Pennsylvanian. C₄ photosynthesis is, at the oldest, Late Cretaceous and probably younger, matching the radiation of angiosperms into hot and dry environments. The timing of observed increases in plant diversity does not appear to be associated with physiological changes.

Coevolution

The diversification of vascular plants is associated with an increasing number of coevolutionary relationships. Coevolution can be subdivided into two extreme forms: "tight" coevolution, in which the interactions between two closely linked organisms are intimately interdependent resulting in mutual evolutionary influences, and "loose" coevolution, in which the interdependence of two or more species is facultative and transient. Coevolution includes interactions in which all parties benefit and interactions in which one party benefits at the expense of the other.

The fossil record suggests tight coevolution is rare or short lived. For example, Abert's squirrel currently feeds almost exclusively on ponderosa pine, which currently has a very large geographic range; the modern distributions of Abert's squirrel and ponderosa pine closely overlap. However, Betancourt and Van Devender (as cited in Brown, 1995) suggest that this is a very recent feature since the geographic range of ponderosa pine was reduced to a handful of relict populations in the Pleistocene that probably could not have supported a viable squirrel population. Likewise, there are many angiosperm genera whose fruits or seeds are currently dispersed by specific mammals or birds. Although many of these genera had similar seed and fruit morphologies more than 30 million years ago, none of their modern dispersal agents existed during this time. In fact, these plant lineages passed through two major turnovers of mammals during the Tertiary, indicating that dispersal coevolution must have been either loose or capable of rapid adaptation. Additionally, recent analyses indicate that the radiation of the angiosperms had little apparent influence on the diversification of insect families, although it is possible that coevolutionary response occurred below the family level. In fact, insects began radiating more than 100 million years before the ascendancy of angiosperms (Labandeira and Sepkoski (1993) as cited in Rosenzweig, 1995). These observations suggest that many of the tight coevolutionary couplings seen in modern communities may be relatively transient phenomena.

Nonetheless, both neo- and paleontologists have shown that loose coevolutionary relationships have been an important part of plant evolution. Insect pollination is a basal feature among angiosperms and their closest relatives. Many floral features, including bilateral symmetry, prolonged calyx tubes, nectar and resin rewards, and sympetaly, appeared by the Turonian and suggest specialization for bee pollination (Crepet, 1996). The obligate mutualisms between yuccas and yucca moths, which have been well documented by molecular data, indicate that the general relationship was likely established as long as 40 million years ago. Similarly, fossils indicate that the close association between figs and wasps is at least as old (Pellmyr, 1999). Coevolutionary relationships with pollinators and seed dispersers probably enabled the angiosperms to maintain broadly dispersed but rare or patchy populations by promoting genetic outcrossing and minimizing local inbreeding. This created an opportunity to colonize habitats that were inaccessible to older plant clades that were more reliant on wind and water for the dispersal of seeds and gametes. Further, the presence of mycorrhizal fungi in the earliest plant communities supports the hypothesis that fungi played a key role in allowing plants to spread over terrestrial habitats (Selose and LeTacon (1998) as cited in Bateman *et al.*, 1998).

As suggested in the Red Queen hypothesis, coevolution can result in an apparent “evolutionary arms race” in which both participants are evolving “as fast as they can” only to maintain their relationship relative to each other (Van Valen (1973) as cited in Brown, 1995). Ehrlich and Raven (as cited in Ricklefs and Schluter, 1993), for example, suggested that advances in antiherbivory compounds by plants are matched by the evolution of more efficient detoxification mechanisms by herbivores. Fossil evidence for this kind of coevolution is difficult to obtain. One possible example involves seeds of *Zanthoxylon* (Rutaceae), which possess oils commonly interpreted as deterrents. Such seeds are commonly found pierced by a hole of consistent morphology from approximately 40 million years ago. In extant *Zanthoxylon* seeds, bruchid beetle larvae create similar holes. This suggests a pest–host relationship that has persisted for approximately 40 million years. Nevertheless, it is unknown if such an arms race of evolving strategy and counterstrategy occurred during this period.

The paleoecological perspective also provides evidence for a very broad coevolution between vertebrate herbivores and plants. Vertebrate herbivory appeared in the Pennsylvanian and became well established by the Permian. During this time a terrestrial food pyramid of plants and synapsid herbivores was established, lasting to the Early to mid-Triassic time. These herbivores became extinct during the Middle Triassic and, after a brief hiatus, were replaced by dinosaurs. From the Late Triassic through to the end of the Cretaceous, dinosaurian herbivores dominated. Some of these herbivores were small (on the order of 30 kg), but the dominant ones were nearly two orders of magnitude larger. At the Cretaceous–Tertiary boundary, average herbivore size plummeted with the extinction of terrestrial dinosaurs and the radiation of birds and mammals.

Although the forces driving turnovers in vertebrates are hotly debated, it is evident that changes in the composition and structure of floras accompanied changes in the

composition of the vertebrate faunas. The Permo–Triassic marked a very broad global transition from floras dominated by pteridophytes and seed ferns to floras dominated by cycadophytes and conifers. This transition resulted in less digestible forage for herbivores, which the fossil record suggests generally favors the evolution of larger herbivores. The radiation of herbaceous and shrubby angiosperms and low-feeding ornithischian dinosaurs during the later Cretaceous again suggests a very broad-scale coevolutionary process. Dense angiosperm communities, spatially well suited to exploitation by small mammalian and avian herbivores, apparently became common only after the extinction of the terrestrial dinosaurs at the Cretaceous–Tertiary boundary. Together, these observations suggest a coupling between community composition and structure and the evolutionary history of large herbivores.

Succession

Succession is one of the most conspicuous processes in the change of community composition and structure over ecological time scales and is one of the most widely written about topics in plant ecology. Because succession involves local immigration and extinction coupled with changes in species relative abundance, it is conceptually tied to the notion of community stability and equilibrium.

As a neocological process, succession occurs during timescales defined by the lifetimes of individuals in populations, which vary across species and the communities they form. It is also dependent on the frequency, duration, predictability, and magnitude of environmental change, the proximity of source areas, and the diversity of life history traits present in the species pool. These features are believed to dictate the apparent orderliness of succession and thus the abundance and diversity of species within a community at any given time (Crawley, 1997).

Succession was minimally important in the earliest land plant communities because they were patchy and composed of taxa with similar growth habits and physiological requirements. By the Late Devonian a variety of clades had evolved shrubs and trees, creating multilevel communities and ushering in light-controlled succession. Other features also affected succession, including nutrient availability, and physical disturbance. Fire-driven succession has been demonstrated for the arborescent lycopod *Sigillaria*, which occurs immediately above charcoal-rich layers in Pennsylvanian swamps.

Succession in Mesozoic gymnosperm communities is more difficult to demonstrate. Retallack and Dilcher (as cited in Niklas, 1981) note that angiosperms and cycadeoids in the Late Cretaceous Dakota Formation tend to be associated with sedimentary features indicative of disturbance, whereas conifers and cycads are generally absent from such environments. Similarly, Hickey and Doyle draw attention to the fact that angiosperms in the Early Cretaceous Potomac Formation appear in otherwise conifer-dominated environments either directly above layers of charcoal (created by fire) or in sediments indicative of disturbance by water (Niklas *et al.* (1985) as cited in Ricklefs and Schluter, 1993). Such angiosperm-dominated localities subsequently revert to conifer-dominated

communities, suggesting that some or all of the earliest flowering plant species were early successional specialists.

Stability and resilience

The stability and long-term diversity of living communities are features of considerable contemporary interest and debate. Discussion of these features, however, is often confused by matters of precise definition. Although recent neoecological debate has focused on the effects of diversity on ecosystem processes, such as nutrient cycling and biomass production, some studies have examined the persistence of taxonomic composition. With reference to taxonomic stability, some ecologists maintain that the more species that are in the community, the more interactions will occur and the more resilient the community becomes to perturbation. A similar argument is made for ecosystem processes. However, a similar number of interactions could occur within a community in which continuous species turnover was occurring, changing the species composition but maintaining species richness and ecosystem processes. Thus, two different measures of the community, taxonomic composition and ecosystem properties such as species richness, could demonstrate conflicting patterns (Haskell as cited in Brown *et al.*, 2000). These features of ecosystems are complex and require careful identification of the appropriate models, definitions, and scales of investigation necessary to define stability and the methods used to measure it.

Within communities, species diversity ultimately reflects the dynamics of local colonization and extinction as influenced by the prevailing physical and climatic conditions, species life histories, and evolutionary clades present. As such, diversity (or species richness) is an emergent property of both ecosystems and evolution. It is the result of a myriad of complex interactions of abiotic and biotic factors. Species diversity per se does not dictate whether or not a community displays stability. However, increased biological diversity may confer an increased array of potential responses to varying environmental conditions. Thus, as diversity increases through increased niche diversification, the probability of including species with tolerances for new sets of environmental conditions also increases. During periods of drastic environmental change, the different capacities for productivity, mortality, reproduction, etc. may allow some community members to survive, or change their relative abundance within the community under the new environmental regime, and thus to produce a similar community under the new regime.

Community stability in the fossil record is primarily gauged in terms of taxonomic composition. However, as data are summed over increasingly long time periods, the level of taxonomic resolution generally decreases. Still, stability may be estimated by rates of extinction and origination, with high taxonomic turnover rates suggesting community instability. Using this gauge, late Paleozoic swamp communities appear to be very stable, changing slowly in the face of increasing global cooling leading to the threshold of the Permo-Triassic boundary (DiMichele and Phillips (1990) as cited in Ricklefs and Schluter, 1993). These communities contained large numbers of pteridophytic and early seed plant species, each of

which offered a different “solution” to environmental change. With the transition to the generally continental climates of the early mid-Mesozoic, conifers, cycadophytes, and several other less diverse seed plant clades characterized by slow reproduction and growth rates replaced the Carboniferous swamp communities, but at a lower level of species diversity. However, despite their comparatively low diversities, these floras never experienced substantial extinction events, suggesting that taxonomic diversity and stability are not inevitably linked to one another. Similarly, even though the evolution of angiosperms led to arguably the most diverse communities in Earth history, there is no indication from origination/extinction rates that angiosperms form more or less stable communities than their predecessors.

Instead, it is possible that rates of compositional turnover may be more heavily influenced by rates of environmental or evolutionary change and independent of ecosystem function, taxonomic composition, or species richness. For example, climatically driven migrations observed in the late Pleistocene raise the possibility that species are constantly shifting in response to stimuli and may repeatedly reassert themselves into similar associations. The players may be the same over long periods of time, but the communities are not stable in the sense that we would discuss them in a neoecological context. The relative stability of communities observed from the Paleozoic to the present may suggest that most communities are relatively stable in the face of “normal” Earth change. It may take catastrophic change to destabilize the community, regardless of the diversity.

From the perspective of individual lineages, the fossil record suggests that those clades including species with a range of growth habits appear to be more long lived than clades possessed of but one growth habit. Additionally, large organisms tend to be more insulated from rapid changes in the environment and to respond to longer temporal oscillations in the abiotic environment that may be unavailable to smaller plants with shorter life spans. However, small organisms can respond rapidly to short-term environmental changes. If a clade is represented in a community by species with large and small body sizes, then that clade could persist in a community, despite short- or long-term changes in the environment, thus giving the community the appearance of taxonomic stability when gauged at the higher taxonomic levels.

Diversity Equilibria

Many experiments have apparently demonstrated short-comings in the original theory of island biogeography, especially regarding the idea that island species richness is maintained at consistent equilibrium values by colonization and extinction (MacArthur and Wilson, 1967; Rosenzweig, 1995). However, there is increasing evidence that colonization and extinction processes may be important in maintaining an equilibrium in systems in which species composition is not severely limited by low colonization probabilities (Brown *et al.*, 2000). For example, European pollen data show that there is no overriding directional trend in plant family diversity throughout the past 10,000 years at 24 European sites located between 40 and 70°N latitude. Eighteen of the 24 sites

examined show remarkably consistent diversity despite high rates of familial turnover at each site of 30–50% per 1000-year interval (Haskell as cited in Brown *et al.*, 2000).

Testing theories about diversity equilibria over the longer time spans of the pre-Quaternary record is fraught with potential sampling and taphonomic pitfalls (Alroy (1998) as in McKinney and Drake, 1998). Nonetheless, diversity equilibria models have been extended to evolutionary timescales (Sepkoski, 1991). In these models, diversity is hypothesized to be ultimately limited by rates of speciation and extinction. Equilibrium in this case is hypothesized to be due to “niche saturation” and occurs when a clade has exploited all possible opportunities.

For several animal clades, at intermediate timescales, species origination rates appear to be richness dependent, whereas extinction rates are not. Thus, as diversity increases, origination rates decline and diversity reaches an equilibrium number (Rosenzweig, 1995; Alroy (1998), and McKinney (1998) as in McKinney and Drake, 1998). A similar pattern is also observed in the plant fossil record. During the initial debut of each major land plant clade, speciation rates tend to be high and species longevity is short, but subsequent rates of origination tend to decrease while species longevity increase (Figure 3). Furthermore, extinction rates have remained essentially independent of standing diversity (Figure 4). Species diversity equilibria, however, are attained only for short and intermediate intervals of geological time. Over longer periods, diversity has progressively increased (Figure 3). It is not difficult to understand why: Species equilibria require stable environmental conditions and an unchanging field of

players. Over geologic time, neither occurs for a variety of abiotic and biotic reasons, such as plate tectonics evolution.

Latitudinal Gradients

An important macroecological pattern of diversity is the latitudinal diversity gradient, which is the increase in alpha and beta diversity from polar to tropical regions. This gradient is reflected by both the number of higher taxa and the number of species nested within those taxa (Ricklefs (1989) as cited in Ricklefs and Schluter, 1993). For example, typically there are approximately 1.4–2.3 species per plant family and 12 plant families per 0.1-ha area plots within temperate tree communities. In contrast, tropical tree communities of the same size have between 2 and 4 species per family and as many as 58 families (Gentry (1988) as cited in Ricklefs and Schluter, 1993). Evidence from the fossil record suggests that a latitudinal gradient in angiosperm diversity has existed since the origin of this clade. The Eocene floras of 40–50° N latitude were more diverse than those at 70° N latitude during this relatively warm geological interval. The same pattern is seen when comparisons are made among 20- to 16-million-year-old floras found in eastern or western North America and the Canadian Arctic.

Many hypotheses have been advanced to explain the latitudinal gradient in species diversity. The most promising propose multiple processes and consider both local- and global-scale patterns, invoking gradients of productivity and energy availability that correlate with changes in latitude

Figure 3 Origination rates of vascular plants. Origination rates of pteridophytes, gymnosperms, and angiosperms are plotted as a function of geological time. Curved line denotes ordinary least squares regression for total standing diversity. Rates are computed as the appearance of new species per unit time (relevant geological stage) per standing local diversity. Exceptionally high rates at the appearance of each group reflect low standing diversity of the group at first appearance. Data from Niklas KJ (1997) *The Evolutionary Biology of Plants*. Chicago: Univ. of Chicago Press.

Figure 4 Extinction rates of vascular plants. Extinction rates of pteridophytes, gymnosperms, and angiosperms are plotted as a function of geological time. Curved line denotes ordinary least squares regression for total standing diversity. Rates are computed as the disappearance of new species per unit time (relevant geological stage) per standing local diversity. Exceptionally high rates at the appearance of each group reflect low standing diversity of the group at first appearance. Data from Niklas KJ (1997) *The Evolutionary Biology of Plants*. Chicago: Univ. of Chicago Press.

(Brown, 1995). Productivity ultimately controls biodiversity, and conditions that favor high productivity, such as warm temperatures and ample precipitation, are often associated with high diversity (Currie and Paquin (1987) as cited in Rosenzweig, 1995).

Differential origination rates from the tropics to the poles may also play an important role in creating and maintaining the latitudinal diversity gradient, although a fundamental mechanism for this pattern has yet to be identified. In general, it appears that major evolutionary innovations and speciation events occur more frequently in lower rather than higher latitudes and that these innovations subsequently spread toward the poles over comparatively long periods of time. The hypothesis of the equatorial region as a source of novelty is supported by trends in the invasion of land, the origin of seeds and angiosperms, and even the invasion of land by tetrapods, all of which appear to comply with a “tropics to the poles” trend (Jablonski, 1993).

Abundance

As ubiquitous as the latitudinal diversity gradient but possibly more mysterious are the patterns of abundance that are found in both modern and historical communities. Although it is generally agreed that increasing resource availability can increase diversity, very little is understood about how these resources are divided among members of a community. Abundance patterns in extant communities tend to conform to a “canonical” pattern: Most species are rare, whereas very few are common (Preston (1948, 1962) as cited in Brown,

1995; Rosenzweig, 1995; Rosenzweig (1998) as cited in McKinney and Drake, 1998).

Unfortunately, examination of past abundance patterns is confounded by preservational features. The plant fossil record consists of plant parts (dispersed leaves, fruits, wood, etc.) that are preserved in a manner that imperfectly reflects the abundance of species in communities. A deciduous tree, for example, within an otherwise evergreen forest might appear to dominate due to excessive production and shedding of organs. However, several Tertiary floras and a few Carboniferous ones are both geographically extensive and widely sampled, and they suggest that canonical abundance distributions may be a common feature in historical communities.

Dominance within a community, as reflected by abundance, appears to be a transient feature for an individual species. Indeed, the fossil record indicates that most species that were once common typically become rare with time (Knoll (1986) as cited in Rosenzweig, 1995). At a higher taxonomic level, however, certain groups do exhibit long-term dominance (e.g., the Mesozoic is the age of conifers and cycadophytes). This dominance likely reflects the increased genetic, developmental, morphological, and reproductive diversity inherent in pooling larger numbers of species within higher taxa. When members of a clade breach a developmental barrier, radically new solutions to life may arise that may allow for increased abundance via the colonization of new environments and/or the ability to outcompete with older clades. This dynamic may account for major transitions in dominance such as that between gymnosperms and angiosperms (Figure 5).

Figure 5 Changes in floristic composition. Taxonomic composition of representative floras (expressed as the percentage of each major group of vascular land plants) are plotted against geological time. Rhyniophytes and taxonomically “problematic” groups of plants dominate the first land plant floras; angiosperms dominate the most recent fossil plant floras.

Summary

Examination of the major patterns of plant diversity from both contemporary and historical communities holds the promise of illuminating the fundamental mechanisms responsible for the origin and maintenance of biological diversity. Here we have outlined several “rules” and patterns that appear to have been important in the evolution of plant communities. In many situations, the contemporary and historical evidence clearly complement each other. In other cases, such as the relative importance of competition, they appear to conflict. The latter cases may reflect the inherent research limitations of paleontology and neoecology, the real effects of temporal scale, or the operation of different processes.

Of particular note to ecologists interested in diversity should be identification of those factors that cause diversity to change at both short and long timescales. Dramatic climate change and evolutionary innovation appear to be the most important features in the historical record. It is interesting to note that the current diversity–stability debate has considered these variables not as cause but as effect, examining the influence of diversity on community and ecosystem processes

rather than vice versa. We live in the most diverse terrestrial communities in the history of Earth, but they function as the result of the same basic rules of interaction, energetics, and stoichiometry as did their Paleozoic predecessors. When events, human or otherwise, create an extraordinary disturbance, biodiversity may plummet and modern communities, as we recognize them, may cease to exist. However, the evidence of 400 million years strongly suggests that the survivors will reorganize into communities and continue to function following the same basic physical, chemical, and ecological rules that created the world around us. They have done so before, and there is good reason to assume that they will continue to do so as long as this planet harbors life.

Explanation of Concepts and Terminology

Fossil Community—Membership Times

Calculation of residence times is only feasible under rare conditions, of which the two main ones are (i) the availability of a rich and dense fossil record from a restricted area allowing to reconstruct the community history in great detail and (ii) accurate age control of the rock succession that yielded the record. The Miocene in the Calatayud-Daroca basin in North Central Spain (Daams *et al.*, 1999a) meets the two requirements. Thus, van der Meulen *et al.* (2005) disposed of a well-dated, rich record of fossil rodents (~50,000 teeth) from 102 localities ranging from 17 to 10 Ma. Eighty-seven assemblages derived from four sections situated in an area of about 2 km² near Villafeliche (Province Zaragoza). The sections have been firmly correlated lithologically, biostratigraphically, and magnetostratigraphically, and form the framework of the locality succession. Seventeen additional localities are situated in an area less than 12 km away, and have been biostratigraphically interpolated to the Villafeliche succession. The sections in the studied area have been successfully correlated to the geomagnetic polarity timescale allowing the determination of sediment accumulation rates and the estimation of ages for the localities (Krijgsman *et al.*, 1994, 1996; Daams *et al.*, 1999b). The 102 localities form a discontinuous record, because the fossiliferous beds alternate with unfossiliferous and/or unwashable (limestone) ones. The studied assemblages represent the time interval from 16.8 to 10 Ma; the mean temporal resolution (number of localities divided by length of time interval) is about 66,000 years. The densest record is between 16.8 and 12 Ma giving a resolution of 46,000 years; the resolution of the later part (12–10 Ma) is comparatively poor (200,000 years).

van der Meulen *et al.* (2005) reconstructed membership times in two steps:

1. They calculated inferred ranges of the species and species lineages, that is, “modifying the observed taxon ranges by estimating the ends of ranges after the method of Barry *et al.* (2002), to statistically avoid taxon absences owing to insufficient sampling and chance” (p. E110):

$$P_i = 1 - (1 - p_i)^r$$

where P_i is the probability of finding a single specimen of taxon i in the localities adjacent to those containing the observed first or last occurrence (FO and LO); p_i the probability of finding a specimen of the species in the locality containing the last or first occurrence of the taxon; r the number of specimens in the localities for which the probability of taxon i being there is estimated; and r

is cumulative. In contrast to Barry *et al.* (2002) who employed the mean abundance of a taxon over its range, van der Meulen *et al.* (2005) used the frequencies in the localities containing the FO and LO. “In the cases of a gap inside the encountered range of the taxon, the lower frequency found in the localities adjacent to the gap was used. ... Following Barry *et al.* (2002), the absence in a locality is assumed to indicate true local extinction, when the calculated P_i equals 0.8 or is higher (The original text of van der Meulen *et al.* (2005) erroneously states “lower”). The calculated ends of ranges are referred to as inferred first and last appearance (IFA and ILA) to distinguish them from FO and LO yielded by the raw data. The differences between IFA and FO, and ILA and LO are quite variable. Some do not differ at all, and some differ very much. The greatest differences are caused by finds of single elements in very rich localities” (p. E118).

2. All remaining “gaps caused by absence in a single intermediate locality are closed (as they may also result from chance), and only then [they] closed remaining gaps $\leq 200,000$ years” (p. E110). The 200 ky was chosen to average over the extremes of intermediate and small astronomical periodicities and their possible climatic and lithologic influence on the presence or absence of certain taxa. Thus, they assumed to have excluded those temporary absences of taxa, which resulted from the influence of the main astronomical cycles on deposition. Assumingly, the astronomical cycles lead also to habitat shifts; however, the study focused on general trends in community history.

Fossil Communities

The resulting ranges (Figure 1) are interpreted as the residence times of community members, and co-occurring inferred ranges at locality age as the composition of the community existing at that time. The resulting curve of number of community members (N_{mem} , Figure 2) through time represents a signal of community change, because it is not correlated to sample size, and is averaged over climatic and lithologic oscillations.

An assemblage from a single locality represents a past community from which it derived, but the existence of assemblage zones in biostratigraphy indicates that successive assemblages are usefully grouped in higher units, which are recognized spatially to a certain extent. Olson (1952) introduced the term *chronofauna*, “defined as a geographically restricted, natural assemblage of interacting animal populations that has maintained its basic structure over a geologically significant period of time” (p. 181). Today, however, extant communities are generally described as dynamic rather

Figure 1 Observed occurrences (horizontal lines) and inferred ranges (vertical lines) of the 57 Miocene rodent taxa studied by van der Meulen *et al.* (2005). Miocene continental stages in Europe, and their correlation to the timescale (after Daams *et al.*, 1999b) are shown at the left. The entries before 17 Ma and exits after 10 Ma have been taken from the literature (Reproduced from Figure 2 in van der Meulen AJ, Peláez-Campomanes P, and Levin SA (2005) Age structure, residents, and transients of Miocene rodent communities. *Am. Natl.* 165: E110–E125.), with permission from Chicago University Press.

Figure 2 The temporal changes in the numbers of the rodent-community members (N_{mem} , red line) and in CA (dark blue line) based on the record of van der Meulen *et al.* (2005). The two lines mirror each other, illustrating the negative correlation between them, because entries increase N_{mem} and decrease CA, exits may cause the opposite effect (see text). The turnover between LUM3 and MAN is better represented by the CA curve than the N_{mem} curve, because after ~ 13.8 Ma entries and exits are more or less balanced. The two straight lines between FTE and LUM3, and between PJE2 and CAR1, are drawn to compare the CA increase and linear increase in time in these trajectories with N_{mem} loss. The difference between them indicates preferential loss of later arrivals and retaining early arrivals (seniority rule, see text). Abbreviations refer to locality names (Reproduced from Figure 3 in van der Meulen AJ, Peláez-Campomanes P, and Levin SA (2005) Age structure, residents, and transients of Miocene rodent communities. *Am. Natl.* 165: E110–E125.), with permission from Chicago University Press.

than static entities, and the need to use a special term (chronofauna, paleocommunity, and faunal complex) for paleontologically recognized communities seems now less necessary than before. We use Tokeshi's (1999) shorthand for a community, as the continued assemblage of coexisting species, taking "continued" to refer both to ecological and

evolutionary timescales. However, Olson's chronofauna and the Early-Middle and Late Aragonian–Early Vallesian communities discussed by van der Meulen *et al.* (2005) display considerably more compositional variation than an extant community even to the extent that a number of members never coexisted. Therefore, they are perhaps better related to

the metacommunity concept (Wilson, 1992), “a set of local communities that are linked by dispersal of multiple potentially interacting species” (Leibold *et al.*, 2004). The fossil metacommunity may be defined as a temporal set of communities linked by residents, long-term components of the fauna or flora of a certain area (see below). This raises the question: is it possible to delineate the temporal extent of a fossil metacommunity?

Turnover

Turnover refers to intervals of increased rates of taxon gains and/or losses, as a result of which the fauna or flora after the interval significantly differs from the ones before. Immigrations and/or speciation are responsible for the gains, emigration, and extinction for losses. There exists a vast amount of literature focusing on relating taxon turnover with environmental (climatic, tectonic, and volcanic) events of varying magnitudes (see e.g., Barnosky, 2001). Here, we are concerned with the question which turnover events cause the change from one metacommunity to another. Paraphrasing the question “Where does a community begin and end?” (Samuels and Drake, 1997, p. 427), the paleoecologist has to answer the question “When does a community begin and end?” van der Meulen *et al.* (2005) proposed the residents to define their fossil-rodent metacommunities, as these are the most continuous, coexisting members forming a core group of species while accompanying members (transients) come and go (Figure 3). Boundaries between successive metacommunities based on replacement of residents have to be drawn within turnover intervals, and are arbitrary. The turnover between the Early-Middle and Late Aragonian—Early Vallesian metacommunities lasted about 1 My between 14 and 13 Ma (Figure 3).

Community Age

Community age (CA) (Figure 2) refers to the mean of the residence times of the community members at the time of the locality age (van der Meulen *et al.*, 2005). “CA increases linearly when plotted against the decreasing ages of the localities during intervals without entries and exits. Entries inherently cause CA to decrease relative to the linearly expected CA, because newcomers contribute a low value to the sum of the RT_{mem} and simultaneously increase N_{mem} . In terms of its CA, an expanding community is rejuvenating. In contrast, the effects of exits vary depending on whether the RT_{exit} of disappearing taxa are below, above, or approximately equal to CA. In the latter case, there is little or no effect on the linear increase with time; when RT_{exit} is well below (or above) CA, the latter value will increase (or decrease) relative to the linearly expected one. So, disappearances of transient taxa cause true aging (i.e., more than linear increase) of the community, while all entries and the disappearances of long-time residents cause rejuvenation of the community” (p. E113).

Figure 2 shows significant negative correlation ($P < 0.1$) between the number of community members and CA. The preferential disappearances of transients while residents remain during the time of taxon loss, has been termed seniority

Figure 3 The ranges of the Aragonian residents showing the two communities which they define (van der Meulen *et al.*, 2005). The turnover phase which gives rise to a new community takes place between ~14 and ~13 Ma. One out of 14 residents of the earlier community, and six out of 14 residents of the later community, are associated with more forested habitats (Reproduced from Figure G1 in van der Meulen AJ, Peláez-Campomanes P, and Levin SA (2005) Age structure, residents, and transients of Miocene rodent communities. *Am. Natl.* 165: E110–E125.), with permission from Chicago University Press.

rule (van der Meulen *et al.*, 2005). In the paleontological literature, temporal species-richness variation is usually illustrated with curves representing the number of taxa against time (see the N_{mem} curve in Figure 2). However, these curves fail to illustrate intervals of maximal change of community composition, that is, phases of turnover, during which taxon losses are compensated by new entries, the net number of taxa varying very little (see the interval between 13.9 and 13.0 Ma in Figure 2). In contrast, the CA curve keeps dropping because both exits of long residents and entries lower CAs.

Residents and Transients

The distinction of the two components is based in the mean (1.54 My) of all residence times. Out of the 57 taxa, 26 of them with ranges ≥ 1.54 My were called residents, the remaining form the transient group (Figure 4). The histogram of all residence times indicates the existence of three groups, because of a group of six residents with very high persistence (further discussed below).

van der Meulen *et al.* (2005) analyzed the habitat preferences and demographic categories of the taxa recorded in their fossil communities. Residents appeared to be associated with early stages of succession, that is, they are supposed to have lived in open habitats, while transients are associated with later stages of succession, that is, living in more wooded

Figure 4 Distribution of the residence times based on the inferred ranges in **Figure 1**, to show the differences between residents and transients indicated by the low class of 2.0 My just above the mean (blue line), which has been taken as the divide. Additionally, a gap at the class of 4.5 My separates two groups of residents. The one to the right includes those residents of the earlier community, which continue into the later one (see **Figure 1**).

habitats. In ecological succession under stable conditions, early successional species are “transient” and are replaced by competitive later arrivals. To explain the reversed roles in the described fossil record, *van der Meulen et al. (2005)* assumed high degrees of disturbance causing the “competitively superior species to become transients because of their dependence on ephemeral late successional habitats” (p. E118).

Related Concepts in the Literature

Magurran and Henderson (2003) studied a 21-year dataset from an estuarine fish community, and demonstrated that commonness and rarity of the species is related to their permanence in the assemblage. The members could be clearly separated into two abundance–persistence groups: core species (abundant and persistent) and occasional species (rare and infrequent). This distinction of core and occasional species was facilitated by a gap in the distribution of persistence around 10 years. Ecologically, the core species are associated with the estuarine habitat and the occasional species with different habitats. *van der Meulen et al. (2005)* suggested that their residents and transients are long-term equivalents of the core and occasional species. Ongoing research of the present authors shows that relative abundance and residence times of the Miocene rodents of Spain are correlated, and the residence-time distributions shows gaps (**Figure 4**), similar to the results of *Magurran and Henderson (2003)*. Furthermore, as expected by *Magurran and Henderson (2003)*, the modes of the fossil residents and transients are much farther apart than their core and occasional species. The latter authors showed that the arrival of occasional species can be modeled as a stochastic event “often related to unusual weather conditions such as storms or unusually settled and warm periods”

(p. 715). The fossil rodent transients have been related to ephemeral late successional habitats, while the residents are adapted to the prevalent conditions during the Miocene in Spain. The ephemeral conditions have to be taken in the context of evolutionary time: the transient residence times vary between 0.02 and 1.55 My. Furthermore, habitat preferences of the fossil rodents are not known in any detail.

However, perhaps the most significant commonality between the ecological and paleoecological study is their recognition of components among community members on the basis of persistence, abundance, and ecological requirements. *Magurran and Henderson (2003)* argue that “Explanations of species abundance distributions cannot ... be divorced from biology,” and neither can residence time of community members, as we will argue further in the next section.

Residents seem also to be comparable with Sheldon’s long-term generalists, “species with properties that enable them to survive throughout wide environmental fluctuations over geological timescales” (*Sheldon, 1996*, p. 209; *van der Meulen et al., 2005*). In the same paper, *Sheldon (1996)* introduces his Plus ça change model, which “proposes that morphological stasis is the usual response to widely fluctuating physical environments on geological timescales (until thresholds are reached)” (p. 209). Thus, the model predicts a tendency for generalists to show little or no evolutionary change. However, the rodent residents yield another, more complex pattern. Four of the six most persistent lineages (>5.0 in **Figure 4**) belong to the Gliridae (dormice), of which only one (*Armantomys aragonensis*—*A. tricristatus*) underwent modest anagenetic change in size and morphology permitting the distinction of two successive species (*Daams, 1990*). The remaining three glirids (*Microdromys legidensis*, *Armantomys jasperi*, and *Pseudodromys ibericus*) show the morphological stasis expected from the Plus ça change model. However, the two cricetid lineages (*Democricetodon* lineage 2 and *Cricetodon-Hispanomys* lineage) do show considerable evolutionary change. For example, the first lineage, recently revised by *van der Meulen et al. (2003)*, comprises four distinct species. The second cricetid lineage needs further revision. These, admittedly few, examples do illustrate that the Plus ça change model, even though it is worded cautiously, needs to be refined.

It is also noteworthy, that the mentioned glirids and cricetids differ in their abundances. While the last often dominate the assemblages, the first do not in spite of their long persistence. So, it may be that phylogeny plays a role in explaining abundance adding further weight to the above quoted conclusion of *Magurran and Henderson (2003)*.

Van Dam et al. (2006) studied a long (20 My) small mammal dataset including the record used by *van der Meulen et al. (2005)*. The former authors estimate that some 80% of the FO and LO of lineages may be close to the ages of speciation and true extinction. They demonstrate that origination, extinction, and turnover rates constitute turnover cycles with periods of 2.4–2.5 and 1.0 My, which are linked to low-frequency modulations of Milankovitch oscillations (*Laskar et al., 2004*). Pulses of turnover occur at minima of the 2.37 My eccentricity cycle and nodes of the 1.2 My obliquity cycle, which are both associated with expansion and cooling and affect regional precipitation. This “correlation between

orbital configurations, climatic events and rodent turnover strongly suggests that the latter is controlled by astronomically forced climate change" (Van Dam *et al.*, 2006, p. 690). This new astronomical hypothesis is consistent with the Court Jester (Barnosky, 2001) and Turnover Pulse hypothesis (Vrba, 1985) "in the sense that lineage events tend to cluster and that the clusters correlate to abiotic events" (Van Dam *et al.*, 2006, p. 690). A finding of interest to community residence times is that most turnover maxima are associated with an increase in the proportion in the short-lived species as indicated by the simultaneous occurrence of peaks of standing diversity and troughs in the mean lifespan per 0.1 My. Standing diversity is based on counts of those taxa that cross the boundaries of the intervals used (0.1 My in this case); taxa restricted to the interval are ignored. Mean lifespan is the mean of the total ranges of the lineages present at each 0.1 My interval. This relationship may be explained by the seniority rule (van der Meulen *et al.*, 2005). Seniority refers to the tendency that during episodes of community member loss later arrivals (transients) are the first to disappear, while residents are preferentially retained and continue the community. Thus, peaks of diversity are caused by transients and troughs represent the remaining residents.

Jackson and Erwin (2006) surveyed the literature for analyses of the fossil record that provide rigorously documented patterns to explore "the dynamics and underlying processes of ecological and evolutionary change in deep time" (p. 322). As to community membership they found that it is "commonly more stable and persistent than expected by chance, even in the face of the extreme environmental changes of the Ice Ages, ..." taken from appropriate examples from reef studies (Pandolfi, 1996, 2002; Pandolfi and Jackson, 2001; Aronson *et al.*, 2004) and small mammals (McGill *et al.*, 2005). These studies are based on comparisons of Pleistocene community compositions with a far greater resolution than the fossil rodent study from which the residence groups were derived. Tokeshi (1999) correctly notes that community persistence (and resistance and resilience) depends on the definition of a community one adopts, and that, therefore, there is "no universal formula for assessing community persistence" (p. 354). However, in the reef studies community membership was compared with random sampling of the habitat-specific species pool, and McGill *et al.* (2005) adopted the neutral theory (Hubbell, 2001) as the null hypothesis to evaluate community similarities. The use of residents and transients is an alternative approach to these studies.

Concluding Remarks

Special conditions of Spain, being a peninsula with a generally dry climate (also during the Miocene, e.g., Daams *et al.*, 1999), have enabled the distinction between residents and transients, and make it an interesting area to study community dynamics. Astronomically forced humidity changes are reflected in changes of species numbers, which are higher during the more humid and lower during the more arid phases (Daams *et al.*, 1999, and literature therein; van der Meulen *et al.*, 2005; Van Dam *et al.*, 2006). The early successional residents are adapted to the typical Spanish conditions. During the

more exceptional humid episodes, succession may advance to later stages and transients enter the communities, in which they generally do not replace but are added to the residents present.

Glossary

Adipocytes, brown Specialized thermogenic cells unique to mammals and probably derived from skeletal muscle that contain numerous mitochondria and small droplets of triacylglycerols. Under neural and endocrine control, brown adipocytes can switch rapidly from inactivity to the highest known metabolic rate, generating heat from oxidation of fatty acids and/or glucose in mitochondria uncoupled from ATP synthesis by uncoupling protein 1. Thermogenesis can be very high in neonates and during emergence from hibernation or torpor.

Adipocytes, white Large cells unique to vertebrates that store triacylglycerols, take up and release fatty acids, produce various signal molecules and receptors that enable them to respond to circulating and locally acting agonists.

Adipose tissue, white Storage tissue unique to vertebrates and best developed in tetrapods that consist almost entirely of expandable adipocytes (q.v.) that contain a large droplet of triacylglycerols, plus vascular and neural tissue, and often contiguous or interchelated lymphoid tissues.

Blubber Specialized superficial adipose tissue found only in pinnipeds (seals), cetaceans (whales and dolphins), and

sirenians (sea-cows) that serves as thermal insulation as well as for energy storage.

Fat body Storage tissue of arthropods that stores lipids and has endocrine and immunological functions.

Fatty acid Any of hundreds of different aliphatic hydrocarbons with an acid group. The main differences are the number and position of one or more double bonds, and the presence of substitutions and side-chains. Most fatty acids are incorporated into larger molecules with ester bonds.

Glycogen An insoluble polymer of glucose. The main storage carbohydrate in animals.

Polyunsaturated fatty acid Fatty acid with two or more double bonds in the chain of carbon atoms. They occur in distinct families defined by the positions of the double bonds, of which the commonest are *n*-3 and *n*-6.

Saturated fatty acid A fatty acid with the maximum complement of hydrogen atoms and no double bonds between carbon atoms.

Triacylglycerol Ester of glycerol and three fatty acids. The commonest lipid storage molecule in animals and green plants.

Introduction: What can be Stored?

Few organisms have continuous access to nutrients derived from feeding or generated by photosynthesis, so some storage is necessary. Many organisms have tissues, cells or molecules adapted to this role.

Specialized storage molecules are insoluble, compact, and nontoxic to the holding cells, even in large quantities. Thus oxygen, which is weakly soluble in water and can be toxic at high concentrations, is stored in substantial quantities only when bound to special pigments in blood or muscle. Vertebrates and some invertebrates and microorganisms can hold oxygen bound to the iron-containing protein, hemoglobin in body fluids. Vertebrate cardiac and skeletal muscles contain the closely related oxygen-binding molecule, myoglobin. However, even specialized diving animals such as seals and whales, whose muscles are dark red with abundant myoglobin, can store enough oxygen to support strenuous activity for about an hour at most. Stores held by sedentary animals are used more slowly so may last longer, but storage capacity for oxygen is still very minor compared to that of other nutrients.

Many vitamins and essential minerals, including iron, are too toxic to be stored in more than small quantities, and then only when bound to specialized proteins, usually in the liver. Calcified skeletons can serve as stores of calcium and phosphate in many arthropods and vertebrates. In female mammals, bone is laid down before breeding and withdrawn during lactation, as the minerals pass to the offspring in the

milk. However, the quantities so stored are limited by the extra weight of dense minerals and the need to maintain normal functioning of the mother's skeleton.

The materials stored by the widest variety of organisms and in the largest quantities are those that can be broken down to provide metabolic energy. Energy-providing molecules that animals can safely store in large quantities are the complex carbohydrate, glycogen, and di- or triacylglycerols, esters of glycerol, and two or three fatty acids. Green plants store carbohydrates as insoluble starch especially in roots and other underground structures and especially in seeds and certain fruits, lipids as triacylglycerols. The complex carbohydrates generally require less energy for synthesis but their associated water makes them denser and less compact than lipids. Glycogen, a common short-term energy store in invertebrate tissues and in vertebrate muscle and liver, is always associated with large quantities of water.

Lipid molecules have such high affinity for each other that they form compact, almost water-free droplets of significantly lower density than other cell components. Comparative studies of angiosperm seeds and fruit, yeasts and various animal cells show that the intracellular mechanisms of the formation of lipid droplets are essentially similar in all eukaryotic cells (Murphy and Vance, 1999); the process is just greatly exaggerated in adipocytes. Lipid droplets arise from specialized regions of the endoplasmic reticulum and are controlled by specific enzymes and other associated proteins, called oleosin in seeds and perilipin in adipocytes.

Lipid synthesis and reclamation are biochemically quite complex and usually slower than the corresponding process of carbohydrates. While carbohydrates (and the glycerol component of lipids) can be broken down by aerobic or anaerobic metabolism, long-chain fatty acids must be oxidized aerobically, so storage lipids can only fuel prolonged, strenuous activities in animals in which the uptake and transport of oxygen are highly efficient.

Most animals can synthesize glucose from amino acids released by the breakdown of proteins but the process is slow and wasteful (because the amino groups have to be excreted). Small amounts of protein and free amino acids, particularly glutamine, may exist in the liver “only” as a storage material for use as precursors for the synthesis of proteins and nucleic acids as well as for glucose production, but most protein utilization entails “wasting” of lean tissue. The associated loss of function is particularly obvious when muscles are broken down to make glucose but protein depletion may also impair the immune and digestive systems. These deleterious effects mean that, especially in animals that have dedicated storage tissues for carbohydrate or lipid, proteins are usually only reclaimed for energy production when the other reserves are nearly exhausted.

Storage in Invertebrates

Many invertebrates are capable of surviving long periods without food. Many unicellular organisms and lower invertebrates have intracellular storage molecules and organelles that contain sufficient energy-generating material to sustain them for hours or days. In prolonged starvation, the body fabric, including structural proteins, is broken down to produce metabolic energy. The first to be reabsorbed are usually reproductive tissues, early embryos as well as gametes, but at least in less complex invertebrates, skeletal, locomotory, and digestive tissues can all be utilized if necessary. Some animals can shrink to an impressive extent while remaining capable of normal life functions and rebuild their bodies when food becomes available. For example, after 4 months of starvation, the medusae of the hydrozoan jellyfish *Aurelia aurita* shrink to less than a quarter of their original diameter but they continue to swim and can regrow if adequate feeding is restored. The ability to retain more or less normal functioning after prolonged starvation may be one of the advantages of the simple cnidarian body plan. More complex animals that have hard skeletons cannot lose so much body fabric without serious impairment of function.

Like vertebrates, higher invertebrates have specialized storage tissues that sequester energy-providing molecules at much higher concentrations than is normally possible when materials are stored in cells with other primary functions. Annelids, especially oligochaetes, have variable quantities of chloragogenous tissue (so-called because cell inclusions confer a green or yellow color) in the coelom around the intestinal wall. It has several functions, including that of storing lipids and glycogen and may be ancestral to the arthropod “fat body” or “hepatopancreas” as it is known in crustaceans.

The insect fat body is the most thoroughly studied invertebrate storage organ. It is present in larval as well as adult

insects and, although originating in the abdomen, it can grow to be massive, extending into the thorax where it surrounds the major locomotory muscles. The stored lipids confer a white or yellow color when replete, as in locusts before migration and many other species before metamorphosis, but the proportion of lipid is rarely as high as it can be in adipose tissue of laboratory rodents. Storage lipids reach the muscles and other tissues as diacylglycerols or triacylglycerols in lipoproteins called lipophorins (Canavoso *et al.*, 2001).

Several hormones involved in energy metabolism and activity were shown to be secreted from the fat body in the 1950s and 1960s, leading to the suggestion that the insect fat body had gland-like functions comparable to those of the vertebrate liver. In *Drosophila* (Arthropoda, Insecta, Diptera), the fat body secretes several peptide regulators of metabolism and appetite that function remarkably like insulin-like growth factors in vertebrates (DiAngelo and Birnbaum, 2009). The fat body also contributes to innate immunity: when stimulated by bacterial extracts, *Drosophila* fat body cells produce at least seven antimicrobial peptides (Manfrulli *et al.*, 1999). Like vertebrate adipose tissue, invertebrate storage organs are much more than just repositories; they play an active role in energy metabolism and defense against disease.

Modern genetic techniques demonstrate remarkable similarities in the signal molecules regulating anatomically diverse storage tissues in invertebrates. Insulin is an ancient signal molecule known in *Caenorhabditis elegans* (Nematoda), arthropods, and all vertebrates (Watts, 2009). Most of the signals and receptors shown to be regulators of appetite and energy storage in mammals are known in the sea squirt *Ciona* (Ascidia, Chordata), an invertebrate chordate. Neuropeptide Y belongs to an ancient family of peptides that mediate signals between storage cells and the nervous system in various invertebrates.

Plants

The aerial structures of many temperate-zone and arctic plants die back in winter when cold or lack of light makes photosynthesis inefficient. Regrowth the following spring is supported by storage materials distributed through roots and surviving parts of the stem, which may be enlarged to form corms or tubers in some species. These structures are not severely limited in volume and density, so the storage material is nearly always starch with much associated water. Only a few higher plants, notably sugar beet (*Beta vulgaris*), store large quantities of disaccharides or monosaccharides. Such concentrated nutrients are often protected from herbivores by stout mechanical casings or by the presence of toxic secondary compounds. Removing or inactivating these plant defenses by leaching (e.g., cassava, *Manihot esculenta*) and/or cooking (e.g., potatoes, carrots, onions) were among the major technological advances of prehistoric humans, and greatly increased the range and nutritional quality of plant foods available to them.

Energy Storage in Seeds

The chief function of energy stores in seeds is to supply the germinating seedling until it grows its own leaves and can

photosynthesize for itself. The huge range of sizes of seeds is due mainly to the chemical composition and abundance of their storage material. The storage materials of the seeds of trees native to cool or cold climates, such as acorns, beech-nuts, and hazelnuts, are usually starches, as are those of grasses such as oats, rye, wheat, and rice. Seed starches generally contain less water, and so are more compact, than those found in vegetative storage tissues, and like them are often protected from herbivory by toxins. The need to compress a lot of storage material into a small space makes synthesizing triacylglycerols from primary photosynthetic products worthwhile, and the storage materials of many large, longer-lasting seeds that are dispersed by animals are lipids, or mixtures of carbohydrates and lipids.

Green plants have a special biochemical mechanism, not known to be present in animals other than a few kinds of parasitic worms, that permits the incorporation of fatty acid carbon atoms into precursors for the synthesis of glucose, which is the starting point for the formation of the structural carbohydrates. Thus plants can convert the fatty acid components of seed lipids into stems and leaves that synthesize sugars in sunlight as well as oxidizing them in mitochondria or incorporating them into structural or storage lipids. Probably because of this additional role, seed lipids contain a much wider variety of fatty acids than animal storage fats (Murphy, 1994).

The triacylglycerols in seeds are always dispersed into tiny membrane-bound compartments called oil bodies, each only a few micrometers (thousandths of a millimeter) across at least some of which contain lipases that enable plant storage lipids to be mobilized quickly. Such structures contrast with the (relatively) huge droplet of triacylglycerols in vertebrate adipocytes that may be greater than 100 μm (0.1 mm) in diameter, or up to a million times the volume of oil bodies in seeds, and explain why nuts do not feel or taste as "greasy" as vertebrate adipose tissue and purified oils do, even though many are greater than 50% by weight lipid. Mobilization of seed storage materials begins at germination with the uptake of water that swells the proteins and starches. Preformed enzymes are activated and new ones synthesized, but, as in the case of animal systems, water-based enzymes cannot easily attack large droplets of lipid.

Chemical Composition of Plant Lipids

The temperature at which major physiological processes like seed germination take place seems to be the most important determinant of the composition of plant lipids. Most biochemical reactions take place in solution so the reactant molecules must be dissolved in liquid for metabolic processes to proceed. Unsaturated fatty acids make phospholipid membranes more fluid, so other molecules can move within and across them more readily and lower the freezing temperature of triacylglycerols. Complete breakdown of unsaturated fatty acids releases slightly less metabolic energy (about 1–2% less for each double bond) than the saturated equivalents with the same numbers of carbon atoms. Triacylglycerols containing saturated fatty acids also pack more neatly (i.e., they have higher melting points), than those

containing mono- and polyunsaturates, and homogeneous assemblages solidify at higher temperatures than mixtures. So in general, more energy can be stored in a small space as saturated triacylglycerols, the more homogeneous, the better (Pond, 1998).

All the plants in which saturated fatty acids are abundant as storage lipids are native to the warm, equable climates of tropical lowlands. Plants such as coconut, oil-palm, nutmeg, and cacao that live only in hot climates do not need polyunsaturated fatty acids to keep their storage lipids fluid: they can maximize the energy obtainable from the smallest volume of storage organ with triacylglycerols containing mostly saturated fatty acids. Those of the seeds of the cinnamon tree, for example, are up to 95% lauric acid (C12:0), although the fatty acids in the fruit lipids of the same species, and of its relative, the avocado pear, are around 50% oleic acid and 25% palmitic acid, with very few medium-chain saturates, a typical composition for an oily, rather than a fatty, fruit. Large seeds such as oil-palms that contain abundant saturated triacylglycerols provide their seedlings with energy supplies that last them weeks or months.

Plant oils rich in polyunsaturated fatty acids are found in species adapted to temperate climates. Olive trees, with fruits and seeds containing mostly monounsaturated fatty acids, and nuts such as walnuts and pistachios which contain both storage lipids and starch, grow in cooler climates than that required by oil-palm or cacao, but are still not worth cultivating for their oil outside areas that have long, hot summers. Lipids containing mixtures of different kinds of fatty acids remain liquid at lower temperatures than those in which all the fatty acids are similar, so those of nearly all temperate-zone and polar species are mixtures of many different fatty acids. However, several possible mixtures of fatty acids in triacylglycerols may have similar physical properties and each plant may be adapted to germinate under slightly different conditions, so the fatty acid composition of seed lipids may differ between species growing in similar climates. Some species can make major alterations to the composition of their seed lipids according to the climate under which they are growing. The fatty acids of the seeds of the sunflower (*Helianthus annuus*) are 44–72% linoleic acid (18:2n-6), the remainder being mostly oleic acid (C18:1). Those growing in the coolest conditions contain the most linoleic acid, but their total yield is smaller and the crop takes longer to mature (Pond, 1998).

The seeds of the jojoba bush (*Simmondsia chinensis*) are almost unique in that the storage material is a wax, not a triacylglycerol. Jojoba oil is liquid at normal temperatures (in contrast to bees' wax, which is used by bees as a solid) because both the fatty acid and the alcohol components of the wax are long-chain molecules. The fatty acids are mostly (around 74%) C20:1, with smaller quantities of C22:1, and oleic acid (C18:1), and the alcohols also contain 20 or 22 carbons. Although the proportion of lipid in the seeds varies widely between strains and according to the conditions under which the plant is grown, the fatty acid composition of the wax, in contrast to that of triacylglycerols, is remarkably constant. Jojoba oil, like other waxes, is indigestible to most animals but the plant is cultivated widely in California and other warm, semidesert areas of the USA where the extracts are used as

lubricants and in cosmetics. Jojoba oil would also be suitable as fuel, so the crop has been proposed as a renewable substitute for gasoline.

Protection from Seed Predators

The lipids and starches concentrated in grains, nuts, and seeds provide a rich source of food for animals including ourselves. The partitioning of seed lipids into tiny oil bodies makes them very digestible for animals because less mechanical emulsification is required. Seed-eating mammals such as rodents gnaw or crush seeds with their hard, continuously growing teeth while parrots, finches, and other seed-eating birds use their powerful, finely controlled beaks to shred nuts and seeds. Fragmented nuts are digestible, highly nutritious food that is especially suitable for flying birds, which cannot afford to carry around heavy gut contents for long periods of slow digestion.

Seeds such as walnuts, almonds, cacao (chocolate) beans, and coconuts protect their nutritious contents with a hard shell (in many species, the nutshell is much harder than the tree's wood) that only the most powerful beaks or persistent gnawing teeth can open. Other nuts, such as peanuts, form underground, avoiding seed predators that cannot dig to reach them. Small seeds such as those of wild strains of flax, sesame, and sunflower scatter as they fall, making it hard work for animals to collect them, and their coats are very tough relative to their size (Pond, 1998).

Many plants have evolved chemical as well as mechanical means of deterring seed predation. Many seeds and/or fruits are rendered distasteful and/or poisonous by the addition of "secondary compounds" some of which are used as sources of flavorings and/or drugs, including caffeine (coffee beans *Coffea arabica*), opium (poppy seeds, *Papaver somniferum*), L-dopa (velvet bean *Mucuna pruriens*), betel nut (*Areca catechu*), and pepper (*Piper nigrum*). Some seed-predators, notably weevils (Insecta, Coleoptera) have evolved specific biochemical mechanisms for detoxifying the secondary compounds of their preferred food plants.

The storage materials of other plants are themselves poisonous to animals. The beans of the castor oil plant, *Ricinus communis*, are protected from herbivory by the poisonous protein, ricin, and by the fatty acid, ricinoleic acid, which can account for over 90% of the storage triacylglycerol fatty acids. Animal lipases cannot easily hydrolyze triacylglycerols containing ricinoleic acid, so most pass undigested through the gut. Eaten in small quantities, castor oil acts as a lubricant and slight irritant, thus relieving constipation in people and dogs and cats, but it is toxic in large quantities. Oil from unimproved oil-seed rape (and turnips, swedes and cabbages, and other Brassicaceae) contains over 40% erucic acid (C22:1) which renders the seeds toxic to weevils and other seed-eating insects as well as to vertebrate seed predators such as voles, mice, finches, and humans. Toxicity is not reduced by domestic cooking. In the West, rape-seed oil (known as canola oil) is produced from plants selectively bred and, more recently, genetically engineered, to form seed triacylglycerols that contain as little as 5% erucic acid. Insects as well as people find the artificially modified plants much more appetizing

than the wild forms, and more pesticides are needed to protect such crops from herbivore damage.

The caterpillars of the cabbage white butterfly feed exclusively on the leaves and flowers of cabbage and related brassicas, including cauliflower, broccoli, and oil-seed rape but they have not acquired more of a taste for erucic acid than mammals have. Even when present in quite high concentrations in the diet, the unusual fatty acid is absent from phospholipids and triacylglycerols in the insects' tissues. Either it is not absorbed through the gut or not esterified into triacylglycerols, or, less likely, it is all used as fuel at once, before it has a chance to become incorporated into structural or storage lipids. Erucic acid even seems to be toxic to the plants themselves: highly specific enzymes direct it into seed triacylglycerols only. None is found in phospholipids or any other nonstorage lipid, suggesting that its presence in such molecules would disrupt membrane function (Pond, 1998).

Vertebrate Adipose Tissue

Proper adipose tissue is unique to vertebrates. It occurs sporadically among fish, often in a greatly modified form, but is most extensive in mammals, birds, reptiles, and amphibians. Its distinctive feature is white adipocytes, which can accommodate much larger quantities of triacylglycerols than any other kind of cell. The formation of single large lipid droplets is mediated by adipose-specific protein 27 (FSP27) (known in humans as cell death-inducing DFF45-like effector C) that is unique to vertebrates. In conjunction with perilipin, it forms an interface between lipids and proteins, promotes lipid uptake and coalescence of droplets while reducing the maximum rate of lipolysis (Puri *et al.*, 2007).

White adipocytes are richly innervated by the sympathetic nervous system and its transmitter, epinephrine (noradrenalin) stimulates lipolysis. Almost all the adipocytes' stores of lipid are not for their own use, but for export to other tissues as required. Not all adipocytes serve solely, or even mainly as whole-body energy reserves supplying tissues via the blood. Most adipocytes secrete and respond to regulators of appetite and metabolism and many are specialized to paracrine relationships with contiguous tissues including the immune and vascular systems (Poulos *et al.*, 2010; Pond, 2011).

The compartmental arrangement of storage lipids found in seeds, brown adipose tissue and many invertebrate storage tissues is not necessary in white adipocytes because such cells do not metabolize significant amounts of their own triacylglycerols. But brown adipose tissue oxidizes its own lipids to generate heat, although when such supplies run low, it can, like most other animal cells, take up metabolites from the blood circulation. The similarity in size and general appearance between plant oil bodies and brown adipocytes may arise from the fact that in both cases, storage lipids are utilized in the cells in which they are sequestered.

As animal cells go, replete adipocytes are huge, thousands of times larger than red blood cells, most brain cells, and the cells of the immune system that protect the body from disease. In **Figure 1**, only the top layer of adipocytes is in the plane of focus and the nucleus, cytoplasm, and lipid droplet cannot be distinguished. Unless severely depleted of lipid, adipocytes are

Figure 1 A thick section of fixed white adipose tissue from an obese adult rabbit. The storage triacylglycerols have dissolved away in the preparation process so most adipocytes appear “empty.” The thin layer of cytoplasm near the cell membrane and extracellular mesh of collagen are stained pink, and none of the small nuclei are visible. The small bright red cells are erythrocytes (red blood cells) in blood capillaries that permeate the tissue. A larger blood vessel is visible at the top left. The adipocytes are roughly spherical but only a few are sectioned through the center thus revealing their actual diameter of about 100 μm (0.1 mm).

spherical, or very nearly so, which is an unusual shape for functionally mature animal cells (other than eggs). Adipocytes are packed in a tight mesh of collagen that also supports numerous blood vessels and nerves. Adipocytes occupy most of the volume of replete, metabolically active white adipose tissue, but extracellular material can dominate lipid-depleted tissue.

Size and Number of Adipocytes

Adipocytes mature from preadipocytes, small cells capable of rapid proliferation and of differentiation into several cell types. Once fully formed and functional, adipocytes are long-lived cells but, like most other cells, they can die by apoptosis, an orderly, often energy-consuming process in which the cells synthesize enzymes that quickly destroy their fabric. In people and sedentary domestic animals, the proportion of lipid in whole adipose tissue is rarely less than 40% and it increases with fattening, reaching as much as 85% of the total mass of the tissue in middle-aged men who are 44% by weight adipose tissue. The rest of the tissue is mostly protein and water. The proportion of lipid is always lower in wild animals, and does not change much with fatness. Dwarf hamsters (*Phodopus*) naturally become very fat during the summer, but chemical analysis shows that their adipose tissue never exceeds 46% lipid, even when it amounts to 35% of the body mass. The proportion of lipid in adipose tissue is almost constant (at 42–66% depending on the depot) in arctic foxes living wild in the high Arctic, whose body composition ranges from 3% to 33% by weight adipose tissue (Pond *et al.*, 1995).

Among mammals and birds (there are no data for other classes), the adipose tissue of larger species consists of fewer, larger adipocytes. Adipocyte number scales to (body mass)^{0.75},

and the adipocytes range in volume from 0.01 nl in bats and shrews, to up to 4 nl in well-fed baleen whales. Carnivorous mammals and ruminants (whose energy metabolism utilizes mainly fatty acids rather than glucose) have about four times more adipocytes than nonruminant herbivores (whose metabolism uses more glucose) of the same size and fatness but they are not fatter because the adipocytes are proportionately smaller (Pond and Mattacks, 1985). By coincidence, the adipocytes of rats and mice, small, nonruminant herbivores, are about the same size (0.1–1 nl) as those of humans, large omnivores on a high-fat diet.

Thorough studies of many specimens of the same species in the wild always reveal much interindividual variation in the total number of adipocytes in the body as a whole, much of which cannot be attributed to age, sex or any obvious feature of dietary history. But adaptations to higher lipid storage that supports prolonged, frequent fasts can be identified. For example, Svalbard reindeer (*Rangifer tarandus platyrhynchus*) live at latitudes 74–81° N and accumulate enough fat during summer and autumn to sustain them during the long winter when only low-quality dry vegetation can be reached by digging through the snow. At the beginning of winter, adipose tissue can exceed 25% of the total body mass, and up to 8 cm thick over the rump but it contains only two to three times more adipocytes than would be expected in temperate zone and tropical deer of similar size.

The number of adipocytes (relative to total body mass) proved to be even more variable in carnivores (Pond *et al.*, 1995). Some arctic foxes (*Alopex lagopus*) and wolverines (*Gulo gulo*) have up to five times as many adipocytes as expected from their overall size, but a significant minority actually have fewer than the expected number. At the time the specimens were collected, there was no consistent relationship between the total number of adipocytes and fatness, measured as the relative mass of adipose tissue in the body. The number of adipocytes in the adipose tissue is not a major determinant of the capacity for fattening. If fewer adipocytes are present, each must expand more to accommodate as much storage lipid as specimens that, for whatever reason, have proportionately more adipocytes.

In humans, and laboratory animals kept under highly artificial regimes of diet and exercise, the number of adipocytes increases with age after sexual maturity, but all these effects are slight, generating at most a doubling of the adipocyte population. They cannot be induced in naturally obese wild mammals such as dormice (*Glis glis*) and there is almost no evidence for an increase in adipocyte number after growth of lean tissue stops in any wild mammal so far investigated.

Anatomical Arrangement of Adipose Tissue

Adipose tissue in most reptiles and amphibians is concentrated in paired depots inside the abdomen, or in the case of lizards on the tail. Adipose tissue in tortoises and turtles is more widely distributed, filling spaces between muscles and in corners of the shell.

Birds have both superficial and intra-abdominal depots. The main superficial depots are at the base of the neck around the furcula (“wishbone”), on the anterior surface of the thigh,

over the breast muscle and on the back near the tail. Biochemical differences between depots in birds have not been as thoroughly studied as those of mammals, but as in mammals, the superficial depots usually enlarge more than the internal ones. They expand laterally as well as thicken, forming an almost continuous layer that is thickest over the back, breast and the anterior surface of the thigh. Over half the body mass can be adipose tissue in birds that fatten before migration or prolonged fasts associated with molting or breeding. A well-studied example is the bar-tailed godwit (*Limosa lapponica baueri*) that flies 11,000 km between New Zealand from Alaska. This small wader starts its journeys with fat reserves amounting to 55% of fresh body mass, occupying space created by selective atrophy of the gut and other nonessential organs (Landys-Ciannelli *et al.*, 2003). Measurements on such "adaptively obese" animals reveal surprisingly low, sometimes undetectable energetic costs of the additional body mass, both in flight and walking (Kvist *et al.*, 2001). Locomotory efficiency is unimpaired by adipose tissue that reaches 32% body mass in Svalbard rock ptarmigans (*Lagopus muta hyperborea*) (Lees *et al.*, 2010).

Mammalian adipose tissue is always partitioned into a few large and many small depots. Its comparative anatomy is based on measurements of the size and number of the adipocytes. Figures 2 and 3 show the patterns of distribution of larger and smaller cells that emerge for various mammals.

Larger adipocytes do not always make larger depots: Some of the smallest depots, such as the popliteal behind the knee, consist of relatively large cells. Nor do adjacent depots, such as those either side of the forelimb, necessarily consist of cells of similar size.

In the adult camel (Figure 3a), over a third of all adipose tissue is in the humps, compared with 4–8% in the corresponding site of hares (Figure 2b), up to 4% in squirrels and a maximum of 1% in stoats (Figure 2c). But less than 1% of the camel's adipose tissue is in the inguinal depot, on the front of the thighs and the sides of the abdomen. This depot contains over a third of the total adipose tissue in stoats and squirrels, more than a fifth of that of the lioness (Figure 3c), and an eighth of that of horses (Figure 3b). There are also contrasts in the proportions of adipose tissue located on the dorsal wall of the abdomen, from nearly half in squirrels and hares (Figure 2a and b), to an eighth or less in the large animals (Figure 3). Although the range of sizes of adipocytes differs greatly between species and between specimens, partly because some specimens were fatter than others, the anatomical pattern of relative sizes of adipocytes is similar in all terrestrial mammals. What differs between species is the relative abundance of adipocytes in each depot: the relative size of their adipocytes forms the same general pattern. Taxonomically related species have similar patterns of distribution of adipose tissue (Pond, 1998).

Figure 2 The organization of adipose tissue in various wild mammals. (a) The gray squirrel (*Sciurus carolinensis*), figures are the means of four specimens, body mass 0.38–0.67 kg, 3.1–14.4% dissectible adipose tissue. (b) European hare (*Lepus timidus scotius*), figures are the means of five specimens, body mass 2.4–3.5 kg, 0.3–3.2% fat. (c) Stoat (*Mustela erminea*), figures are the means of five specimens, body mass 0.19–0.4 kg, 3.2–6.3%. Upper sets of figures are the mean volume of adipocytes in nl (10^{-9} l); lower figures are the proportions of the total dissectible adipose tissue to be found in the depot. The intermuscular depots are shaded. Data and illustration from Pond CM (1998) *The Fats of Life*, 344 pp. Cambridge: Cambridge University Press.

Figure 3 The organization of adipose tissue in some large zoo-bred or domesticated mammals. Data are presented in the same way as in **Figure 2**. (a) Two-humped camel (*Camelus bactrianus*), a pregnant female, body mass 650 kg, 6.1% fat. (b) Domesticated horse (*Equus caballus*); figures are means of measurements from two geldings, body mass, 444 and 570 kg, 5.2%, and 4.0% fat. (c) Pregnant female lion (*Panthera leo*), body mass 167 kg, 13.3% fat. Data and illustration from Pond CM (1998) *The Fats of Life*, 344 pp. Cambridge: Cambridge University Press.

Although a great deal is now known about the biochemical steps by which adipocytes differentiate and mature, almost all of the information comes from the study of cells in culture, so we cannot explain in detail why adipose tissue forms where it does, or what determines the species differences in the relative sizes of the depots. The gross anatomy must have implications for the animals' habits and capabilities because there are site-specific differences between adipocytes in many physiological properties. Some depots seem to be equipped mainly for taking up lipids from the blood after a meal, others for quick responses to the onset of strenuous exercise. Many of the minor depots that enclose lymph nodes may be mainly or entirely devoted to supporting immune processes and contribute little to whole-body energy storage (Pond, 2009, 2011). They are among the first to form during ontogeny and the last to be depleted in starvation. In very lean wild animals, the only replete adipocytes may be those associated with lymph nodes and heart.

Relatively minor depots may be almost undetectable in small animals, especially if the specimens are lean, so perhaps it is not surprising that larger animals (**Figure 3**) should appear to have more "extra" adipose depots for which there are no exact equivalents in the smaller species (**Figure 2**). Some are just too big to be thus explained away: up to a third of all adipose tissue of horses (**Figure 3b**) and donkeys forms a sheet, sometimes several centimeters thick, on the inner ventral wall of the abdomen. There is a small quantity of adipose

tissue in the corresponding depot of large carnivores and camels (**Figure 3a** and **c**), but it is absent in most other species.

In primates, the most conspicuous such depot is the "paunch" that arises from the midline on the outer wall of the abdomen and expands laterally as it thickens, sometimes becoming very thick at the midline, and extending as far as the chest and the hip bones. In humans, the paunch adipose tissue is centered around the navel, usually somewhat thicker above it in men, and below it in women. The paunch depots seems to accumulate fat selectively in primates: It may be minimal in lean (but not emaciated) specimens, but often becomes very massive in humans and in monkeys and apes that become obese in captivity, while the other depots expand more slowly with increasing fatness, or, in the case of the intermuscular depots, hardly at all. An abdominal paunch with these properties seems to be a unique and distinctive feature of this group and is as conspicuous in lemurs (primitive strepsirrhine primates) as it is in apes, indicating that it appeared early in their evolutionary history. In spite of having this "extra" depot, with the exception of modern humans, primates are generally no fatter than other mammals when living under natural conditions (though some may become obese in zoos).

There is no trace of this depot in hares, squirrels or any related small mammal, but Carnivora have a "paunch" depot

on the outer ventral wall of the abdomen. The depot can become thick in cats and their relatives but it is relatively small in canids, ursids, and mustelids. It does not expand disproportionately any more than any other superficial depot, even in very obese wild carnivores such as arctic foxes. Very little is known about the physiological basis of the paunch depot's special properties because its complete absence in rodents precludes convenient experiment study (Pond, 1998).

Measuring Fatness in Wild Animals

Because adipose tissue is the most variable component of the body, the simplest and most widely used measure of fatness is body mass. Body mass index is this measurement adjusted for body length or height. In small animals, the guts represent such a large and variable fraction of the total body mass that such methods are not very accurate or reproducible. If samples of adipose tissue can be obtained by biopsy or post mortem, adipocyte volume is also used to estimate fatness, but such measurements from most wild animals as not as easily interpreted or reliable as experiments on laboratory rodents might suggest. Such data are modulated by the effects of body size and natural diet on the cellular structure of adipose tissue, site-specific differences in adipocyte volume and variability in cellular structure of the adipose tissue.

Figure 4 shows some data on adipocyte volume from wild polar bears. Females (but not males) stop growing when they become sexually mature and fatten enormously during pregnancy, producing a predictable relationship between body mass and adipocyte volume, but the correlation is weak for cubs and males that are still growing because adipocyte number is also increasing. However, these data do illustrate some important aspects of bear ecology: cubs still with the

mother are generally fatter than those of similar size that have been abandoned to forage alone, and there is great variation in the fatness of cubs and adult males, especially among the larger specimens, probably reflecting differences in hunting success.

For children and young people, measuring skinfold thickness with calipers is widely used to assess fatness, but the skin of most mammals is too thick and tough, and the underlying adipose tissue too thin and patchy, for skinfold thickness measurements to be of much use. As wild mammals get fatter, superficial adipose tissue always expands more rapidly than that inside the abdomen. The depots shown in Figures 2 and 3 become thicker and expand laterally to cover a greater area. In very fat specimens, including many humans, adjacent superficial depots overlap and merge so that they become difficult to distinguish, but measurements of adipocyte volume can reveal their identity. Since expanding depots spread out as well as thicken, thickness alone is only a crude measure of the total adipose tissue, even if the site from which the measurements are taken is kept strictly constant. The fatness of small birds is often assessed by inspection and/or palpation of the superficial depots around the neck or leg, a simple method that takes account, at least in a qualitative way, of changes in both the thickness and the area of the adipose tissue.

A high-tech version of skinfold thickness measurements is the ultrasound scanner, which can measure fat thickness fairly accurately in large mammals, especially if, as in pigs, the hair is sparse. The method depends on the fact that sound vibrations travel at different speeds through chemically different materials, and are reflected, producing an echo, at the interfaces between the two tissues. A pulse of high frequency sound is directed into the body from a source placed on the skin, and the timing and intensity of the echo is recorded. Shaving hair

Figure 4 Mean and 95% confidence intervals of the average volume of adipocytes in a sample of adipose tissue from wild polar bears in northern Canada, measured in cubs accompanied by their mothers, weaned females, including pregnant and lactating mothers and solitary males. Data from Ramsay MA, Mattacks CA, and Pond CM (1992) Seasonal and sex differences in the cellular structure and chemical composition of adipose tissue in wild polar bears (*Ursus maritimus*). *Journal of Zoology (London)* 228: 533–544. Illustration from Pond CM (1998) *The Fats of Life*, 344 pp. Cambridge: Cambridge University Press.

is usually necessary and the probe's anatomical position must be consistent. With a resolution of only about 1 mm, ultrasound scanners are not accurate for animals smaller than dogs and for any specimens in which the superficial adipose tissue is very thin.

Lipids are much poorer conductors of electricity than the watery components of cells and body fluids. This contrast is exploited to measure whole-body conductance of electric current as an indicator of the proportion of lipid present. More fat produces lower whole-body conductance. The apparatus has to be used carefully, because hair, feathers, and the pockets of air they enclose also have high electrical resistance, but it is a useful technique, especially for small birds and mammals, and works equally well on living or freshly dead specimens. Fat appears pale in magnetic resonance imaging so this apparatus has been used to study the abundance and anatomical relations of white adipose tissue in humans and, more recently, in sedated domestic livestock and laboratory animals.

With these new techniques impractical for most large animals, dissection is still widely used. For more than 30 years, assessment of lipid reserves in wild vertebrates *in vivo* and post mortem has depended mainly on empirically derived "indices" which are based on the dimensions of the whole body, or that of the thickness or mass of one or a few adipose depots. The sample sites are chosen at random or for some technical reason such as simplicity of dissection. The enormous diversity of sample sites and indices is cumbersome and makes comparisons between studies very difficult and imprecise. One of the favorites is the kidney fat index, the mass of the perirenal adipose tissue as a percentage of that of the kidneys. This index works fairly well for lean deer, antelope and similar ungulates, unless the mass of the kidneys changes seasonally, which can happen in some drought-adapted species. It is less accurate in carnivores (see Figures 2 and 3) in which the perirenal depot represents only a small fraction of the total adipose tissue, and is indistinguishable from that on the rest of the dorsal wall of the abdomen.

Wildlife biologists also try to estimate total fatness of mammals from the lipid content of the marrow in the long bones, thereby eliminating the need for a complete dissection. However, "marrow fat indices" only work on species such as ruminants in which the adipocytes are depleted in starvation. In many other mammals, these adipocytes fail to respond to fasting, probably because they are specialized to support the immune functions of the red marrow.

A further problem with using the mass of one or a few depots as an "index" of fatness is the inherent variability of the partitioning of adipose tissue between depots. In all species for which there are sufficient data, substantial interindividual variation in the relative masses of depots that cannot be attributed to age, sex, or lean body mass is always found, even in genetically homogeneous wild populations and in animals bred and maintained under carefully controlled laboratory conditions. Of the intra-abdominal depots, the dorsal wall of abdomen depot (that includes the perirenal) undergoes the largest changes, especially in deer, sheep, cattle, antelopes, and other ruminant animals: it expands greatly in extreme obesity and shrinks to almost nothing after prolonged starvation. Its anatomical position means that, like the fat bodies of lower

vertebrates, such large, and sometimes rapid, changes in size have minimal impact on the shape or size of any adjacent organs. Depots that contain lymph nodes undergo the least change, so they are relatively massive (compared with those elsewhere in the body) in lean specimens, and relatively small in obese ones.

Adipose Tissue Function

Adipocyte Metabolism

The largest component of replete adipocytes, the lipid droplet, is almost pure liquid triacylglycerols. The thin rind of cytoplasm between the outer membrane and the lipid droplet contains the relatively small nucleus displaced from its usual central position, biochemical apparatus for building and storing receptors, messenger molecules, and enzymes plus a few mitochondria where the fuel that powers their synthesis is produced. Molecular traffic into and out of adipocytes is regulated by a variety of receptors, carrier molecules, enzymes and other substances, most of which are produced by the cells themselves. Until about 20 years ago, adipocytes were known to produce only a few kinds of proteins, but techniques to separate, identify, and synthesize proteins and other biological molecules are rapidly becoming cheaper and more efficient, so biochemists are constantly adding to the list of messenger molecules secreted from adipocytes, receptors that enable them to respond to such signals from each other and more remote tissues, and transport proteins and enzymes that regulate uptake of materials that at least some adipocytes can produce.

Leptin (formerly known as *Ob*-protein) is among the best known secretions of adipose tissue, identified in the early 1990s from the study of a spontaneous mutation that causes severe obesity in mice. This small protein passes from adipocytes (and several other tissues especially those involved in reproduction) into the blood, where it is found in concentrations of around 10^{-8} – 10^{-9} M. It binds to specific receptors on many neurons in the hypothalamus, the region of the brain that controls appetite (and many other drives and emotions). As well as regulating appetite, leptin adjusts energy expenditure and the physiological response to cold. Obesity could be caused by disruption to these chemical signals from the adipose tissue to the brain, leading to chronic overeating and/or very low rates of energy expenditure. Most of the signals and receptors shown to be regulators of appetite and energy storage in mammals are known in the sea squirt *Ciona* (Ascidia, Chordata), an invertebrate chordate. The appetite-suppressing hormone leptin itself seems to be specific to vertebrates, probably appearing early in the evolution of fish, but insects have analogous peptides that signal peripheral energy stores to the nervous system (Gorissen *et al.*, 2009).

Fatty acids cannot be excreted, so any excess has to be deposited in the storage tissues. Most tissues oxidize lipids, with the largest consumers being cardiac and skeletal muscle, the liver, and, especially in neonatal mammals and hibernating species, brown adipose tissue. ATP production in mitochondria is never 100% efficient, some of the energy used becomes heat but "uncoupling" of fuel utilization from the

formation of ATP greatly increases thermogenesis in brown adipose tissue (Cannon and Nedergaard, 2004). Much of the volume of brown adipocytes is occupied by mitochondria so brown adipose tissue is only about 10% by weight storage lipids, which form numerous tiny droplets instead of a single large droplet in white adipose tissue. The fatty acids released by lipolysis are consumed within brown adipocytes for heat production, while those of white adipocytes are released into the blood, where other tissues can take them up and use them.

When fully activated, for example, during rapid warming of the body at emergence from hibernation, brown adipose tissue uses fuels and oxygen at up to 10 times the rate of active muscles, producing enough heat to raise a small mammal's body temperature by more than 2°C h^{-1} (Cannon and Nedergaard, 2004). In the newly born and in awakening hibernators, much of the brown adipocytes' fuel comes from white adipose tissue. The latter's stores therefore determine the animal's ability to maintain its temperature until it can find food: mother's milk or a rich, digestible meal.

Brown "fat" was long believed to be alternative forms of white adipose tissue until the recent demonstration that the pattern of gene transcription in stem cells differentiating into brown adipocytes resembles that of muscle more closely than that of white adipocytes. Brown adipocyte precursors can be detected in skeletal muscle (Crisan *et al.*, 2008) and muscle-specific micro-RNAs can be found in such cells in tissue culture. Nonetheless under artificial conditions, brown adipose tissue can be transformed into white and *vice versa*, and at least in certain species, does so naturally. Many of the sites in which it actively generates heat in newborn mammals contain normal-looking white adipose tissue in the adult. In small mammals that live in cold climates, such as dwarf hamsters, at least some depots consist of mixtures of brown and white adipocytes throughout life, with the thermogenic adipocytes increasing when in animals living continuously in a cold environment, especially if the light/dark cycle resembles the long, dark nights of winter.

Fatty Acid Composition of Storage Lipids

Animals can synthesize the common saturated (palmitic, stearic, and myristic) and monounsaturated (oleic) fatty acids and many can insert an additional double bond into long-chain fatty acids, though this capacity is minimal in higher vertebrates including mammals. Animal desaturases work slightly differently from the corresponding enzymes in plants and microbes, so fatty acids that originate in animals are distinct from those synthesized by primary producers. Except in ruminant animals (in which the rumen microbes alter the fatty acids before they can be absorbed), most fatty acids pass unaltered from microbes or plants to herbivore and from prey to predator.

Recent studies have suggested that the lipid composition of the diet may determine the habits and habitats of poikilothermic animals. The blue-tongued skink or shingle-backed lizard, *Tiliqua rugosa*, is quite common in the deserts of Western Australia. Its natural diet is mainly plants (at least when adult) but also includes carrion and small prey, so it can be maintained on an artificial diet in captivity. After a few

weeks on experimental diets, those given food containing sunflower oil (rich in polyunsaturated fatty acids) chose to spend their days (and nights) in places that were up to 5°C cooler, than those fed on mutton fat (containing mostly saturated fatty acids) (Geiser and Learmonth, 1994). These experiments show that diet can affect important aspects of their ecology, including the times of day at which they are active, and where they forage.

Long-distance migration in birds, especially small species, is among the most metabolically demanding of all activities, fuelled almost entirely by fast, sustained mobilization of storage lipids. Sandpiper (*Calidris pusilla*) demonstrated selective incorporation of dietary fatty acids into structural or storage lipids and evidence for adaptive desaturation that maximizes energy density and efficient mobilization of the storage lipids during prolonged flight (Weber, 2009). However, studies of another species of sandpiper (*Philomachus pugnax*) produced no evidence for similar selectivity of fatty acids mobilized during shivering elicited by prolonged exposure to cold. This comparison suggests that active lipid management entails some physiological cost: the process is essential preparation for migration which requires on precise coordination between muscles during flight but is dispensable for shivering, a more chaotic activity.

Similar investigations on mammals have not yet been performed.

The lipids of cold-blooded animals generally contain a higher proportion of unsaturated fatty acids than those of warm-blooded animals, with species living in colder regions having the most polyunsaturates. Marine algae generally have more highly unsaturated fatty acids than terrestrial plants, and the animals that eat them both incorporate the algal fatty acids unchanged into their own tissues, and elongate and/or desaturate them further. Thus most plants and algae cannot build fatty acids with more than 18 carbons, but many marine animals can elongate oleic acid to form gadoleic acid ($\text{C}_{20}:1n-9$) and various 22- and 24-carbon fatty acids. Gadoleic acid is common in the lipids of many kinds of fish, especially those living at high latitudes. Other fatty acids are also readily elongated, but those of the *n*-6 series derived from linoleic acid are even more unstable (in the sense that they readily participate in chemical reactions, especially oxidation) than those of the *n*-3 series, so the latter are more abundant in the lipids of most marine organisms.

Algae are the basis of nearly all marine food chains, so the storage and structural lipids of almost all animals that feed in or from the sea – ragworms, mussels, oysters, shrimps, crabs, fish, seals, whales, polar bears, gannets, albatrosses, and penguins – are rich in *n*-3 polyunsaturated fatty acids. Such mixtures of triacylglycerols rich polyunsaturates are often called "fish oils," though they are not unique to fish, and the basic fatty acids from which they are derived are rarely produced by fish. The lipids originate in algae but may be modified by animals as they pass up the food chain, eventually reaching top predators such as large fish, sea-birds, and marine mammals. Among the fish used as human food, cool-water species such as herring, sprats, capelin, mackerel, and halibut usually store more lipid than their tropical relatives, because at high latitudes, the supply of most kinds of food changes seasonal and many species routinely live on their fat reserves for weeks

or months. The triacylglycerol fatty acids of large cold-water fish include more monounsaturates than polyunsaturates because they come from waxes that were in the planktonic organisms that they eat. Fish such as sardines and anchovies live in warmer waters where the planktonic invertebrates rarely contain waxes, so their lipids are a rich source of *n*-3 polyunsaturated fatty acids for human consumers.

Some of the food of animals living in lakes and rivers is derived from aquatic algae, but detritus from terrestrial plants and the animals that feed on them also make a substantial contribution, so freshwater fish usually have more fatty acids of the *n*-6 series than oceanic species. The fatty acid composition of the predatory fish follows that of their diet: "farmed" salmon fed on chow made from scraps of slaughtered livestock and other materials originating from the land acquire a correspondingly "terrestrial" fatty acid composition.

As well as being chemically distinct, lipids of marine origin differ in the isotopic composition of the carbon atoms. Slightly different proportions of ^{13}C and ^{12}C are taken up by marine algae that obtain their carbon in solution as bicarbonate, and terrestrial plants that take in carbon dioxide straight from the atmosphere, so organic materials of marine origin contain about 5–7 parts per thousand more of the heavier isotope (^{13}C) than similar molecules from animals that have eaten terrestrial foods.

This effect can be used to investigate the dietary habits of individual animals and populations. Storage fatty acids and cholesterol are particularly suitable because they pass intact up the food chain, are chemically quite stable and only slowly degraded by microbes, so can be detected in excreta and animal remains as well as in biopsy samples. The isotopic and chemical composition of triacylglycerol fatty acids can indicate how much of the diet is derived from marine or terrestrial sources. This technique is particularly useful for widely ranging species with broad, locally variable diets, such as arctic foxes, that are not easily observed in the wild (Pond and Gilmour, 1997). Material from the marrow of buried human and other animal bones, and in coral fragments has been used to study natural diets and food chains.

Mammalian adipocytes can selectively take up and release certain fatty acids (there are no data on those of other vertebrates), making possible seasonal accumulation of triacylglycerols with physical properties appropriate to hibernation (Frank *et al.*, 2008). There are site-specific differences in fatty acid composition of storage triacylglycerols: except in ruminants, the adipocytes around lymph nodes, and to a lesser extent elsewhere in node-containing depots, sequester more polyunsaturates that are essential to the nutrition of the immune system than large nodeless depots. Such site-specific differences must be considered when selecting tissue samples for the study of diet.

Adipose Tissue as Thermal Insulation

The notion that the superficial white adipose tissue insulates the body against heat loss is one of the most firmly established of all dogmas in twentieth century biology, but there is very little evidence that supports it. The hypothesis can be tested by determining whether its distribution and anatomical

arrangement have evolved to carry out such a role more efficiently in animals that need more thermal insulation, because they remain active all winter in cold climates, or habitually swim in very cold water. The mammalian order Carnivora occur in a wide variety of habitats from hot tropics (e.g., desert foxes, jackals) to the Arctic (e.g., polar bears, wolverines, arctic foxes) and almost all are predators, at least to some extent. Carnivora occur in an enormous range of sizes, from stoats and weasels to bears and tigers that can be several thousand times larger, and are therefore suitable for investigating whether species differences in the relative abundance of superficial adipose tissue are determined by habits and habitat or by body size (Pond and Ramsay, 1992).

Figure 5 shows some measurements of the masses of all the intra-abdominal and superficial adipose tissue from various temperate, tropical and arctic carnivores. To ensure comparability, the sample included only specimens that were of similar fatness to the bears. There is a fair amount of inter-individual variation in the partitioning of adipose tissue between internal and superficial depots but overall the mass of superficial depots increases in simple proportion to body mass. In contrast, the intra-abdominal depots become proportionately smaller in larger mammals, whether the animals are native to the Arctic or to warmer habitats.

The surface area over which this larger amount of superficial adipose tissue is spread is smaller in larger animals relative to their volume or mass. The body surface area scales as body mass^{0.66}, that is, it becomes proportionately smaller with increasing body size. With a smaller area to cover, the superficial depots are thicker in larger animals, even if the specimens are not fatter (i.e., if the ratios of the masses of lean and fat tissues are unchanged). The superficial adipose tissue is 10 times thicker in a 500-kg bear than in a 500-g rat or weasel from this effect alone, quite apart from the fact that in larger animals, a greater proportion of the adipose tissue is superficial, and bears are often fatter than rat-sized animals (Pond and Ramsay, 1992).

The measurements from the wild polar bears fall very near to the lines fitted to the data obtained from tropical and temperate-zone carnivores, indicating that the partitioning of adipose tissue between internal and superficial sites arises entirely from the fact that polar bears are very large and lay down large quantities of fat, and has nothing to do with adaptation to thermal insulation. There is no evidence for reorganization of adipose tissue in the smaller species of mammals that have evolved to become aquatic, for example, otters (family Mustelidae) have many adaptations of the trunk, tail, and sense organs to aquatic life, but the arrangement of their adipose tissue is not different from that terrestrial mustelids, stoats, weasels, wolverines, and badgers. Otter fur is oily and less compressible than that of the terrestrial species, so it retains its insulating properties when in water.

These principles are also true of birds. Just before migration or breeding fasts, the superficial depots enlarge greatly, and may become several millimeters thick. They also expand laterally so the depot around the wishbone extends over the anterior part of the flight muscles and along the neck. In swimming animals, indefinite expansion of the abdomen is not compatible with streamlining while in water, but a sleek profile can be maintained if the additional fat is spread out over much of the body.

Figure 5 Allometric comparison of the masses of superficial (solid symbols) and intra-abdominal (open symbols) adipose depots in various species of the order Carnivora. Each point represents a single individual. Squares: Mustelidae (mink, badgers, and wolverines); diamonds: Felidae (cats, jaguars, tigers, and a lion); circles: Canidae (arctic foxes); and triangles: Ursidae (inverted triangles: brown bears). The lines are fitted to all the data *except* those from the polar bears (upright triangles) and fit the equations: superficial depots $\propto$ (lean body mass)^{1.05}, $r^2 = 0.867$; intra-abdominal depots $\propto$ (lean body mass)^{0.81}, $r^2 = 0.873$. Data from Pond CM and Ramsay MA (1992) Allometry of the distribution of adipose tissue in Carnivora. *Canadian Journal of Zoology* 70: 342–347 and additional sources. Illustration from Pond CM (1998) *The Fats of Life*, 344 pp. Cambridge: Cambridge University Press.

This analysis highlights some pitfalls of using measurements of the thickness of superficial adipose tissue as a means of estimating fatness. Fatness is a ratio of masses, the mass of energy stores as a percentage of total body mass, but adipose tissue thickness is a linear measurement. With increasing body mass, the superficial adipose tissue becomes thicker for animals of the same total body composition because the ratio of their surface area to mass decreases. The superficial adipose tissue becomes thicker in larger animals and depots that are adjacent but not contiguous in small species and the juveniles of large species merge in large adults to form a continuous layer, albeit of variable thickness. An almost continuous layer of superficial adipose tissue can create the impression that the specimen is obese, even when the layer represents only a small fraction of the total body mass.

The lactation habit rather than thermoregulation may be the main reason for the massive development of the superficial adipose depots in mammals. Reptiles are usually fattest just before maturation of the eggs begins, and the intra-abdominal fat bodies are much depleted by the time the clutch is ready to be laid. Heavily gravid females are often fasting, so the empty, inactive gut frees up yet more space inside the abdomen. In contrast to egg-lay vertebrates, the demands of lactation immediately follow those of gestation (Thompson and Speake, 2006; Pond, 2011). Most mammals feed normally while they are pregnant and accumulate lipid in preparation for lactation. The reproductive organs and the gut cannot be excluded from the abdomen, but adipose tissue can. The subcutaneous depots may simply be the most convenient place to put a lot of adipose tissue (Klein *et al.*, 2007).

In pinnipeds, cetaceans, and sirenians, the cellular and gross anatomy of adipose tissue is substantially altered to form blubber. Heat conducts through adipose tissue at only a little less than half the rate of muscle or stagnant water and much faster than through fur or feathers. So blubber has to be thick to insulate thoroughly and is satisfactory as the sole form of insulation only for large animals with habits and habits for which weight is not a major problem. Consequently, most small- and medium-sized seals retain fur as additional insulation and extant sirenians and the smallest cetaceans, porpoises, and dolphins, are restricted to temperate and tropical regions. Many of the great whales, for example, humpbacks and fin whales, which feed in polar seas, migrate to warmer waters to give birth to calves that are only a twentieth of their size. Many such places provide little or no food for adult whales, so the mothers fast for several weeks while lactating, drawing on their lipid reserves. The whales do not return to cooler, food-rich waters until their calves have grown large enough and fat enough for blubber insulation to be effective.

Seals are born on beaches or ice floes and most species do not go to sea until they are several weeks old. Neonates have thick coats of fluffy fur but little adipose tissue anywhere, although they fatten rapidly while suckling their mothers' rich, creamy milk. At about the time the seal pups are weaned, the neonatal fur is replaced by shorter, stiffer fur. But fur of some sort continues to make an essential contribution to insulation in all seals except the adults of the largest species, the elephant seals (*Mirounga* spp.). In walrus (*Odobenus rosmarus*), the hair is very sparse throughout life and at birth, the single pup is very large compared with its mother, up to twice the size of

neonatal elephant seals, although as adults, the latter are much larger.

Both these very large pinnipeds occur in cold seas, *Odobenus* in the Arctic Ocean, and one species of *Mirounga* in the northern Pacific including around Alaska, and the other in the Southern Ocean. The skin of walrus hauled out on beaches basking in sunshine is noticeably pink, due to the profuse flow of blood through it and the underlying blubber, which can be up to 15 cm thick. But walrus are a ghostly pale gray when in the sea or exposed to cold weather because the blood is withdrawn from the skin and blubber to the muscles and other warm internal tissues. Blubber can work as an adjustable insulator in this way because blood flow through it can be shut down almost completely for long periods without ill-effects.

If necessary, marine mammals can be very fat. As in the case of penguins, body bulk is only a slight impediment to swimming, and seals and whales can maintain near neutral buoyancy over a wide range of body compositions by adjusting the volume of air in the lungs. The maximum amount of blubber that whales or seals can have without risking overheating during vigorous swimming depends on body shape, the temperature of the water they are living in and how much heat they generate. Marine mammals dissipate excess heat by increasing blood flow through the blubber-free skin of the flippers and tail. On hot days, seals on land sometimes hold up a flipper to the breeze to accelerate cooling. A thickness of about 20 cm seems to be the upper limit. Blubber of that thickness apparently does not hold enough lipid to meet the energy storage needs of the very largest whales, fin whales, blue whales and their relations. They have adipose tissue in the mesentery that supports the gut and around the kidneys, and intermuscular adipose tissue in certain muscles, just as terrestrial mammals do.

Energy Storage in the Life History

Optimizing Energy Stores

Healthy animals living wild usually have around 4–8% dissectible adipose tissue under ideal nutritional conditions but may transiently be much fatter just before some special situation such as breeding, migration or hibernation (Pond, 1998). Many animals that are below 4% dissectible adipose tissue are probably having trouble finding enough food, though not yet in danger of starvation, but for others, having much less adipose tissue seems to be normal. Some common wild animals, such as rabbits, hares, moles, and foxes, seem to live and breed satisfactorily with less than 1% of the body mass being adipose tissue.

The concept of costs and benefits to accumulating fat stores has led to much theorizing about the ecological conditions that might define optimum fatness, and how they change during the animal's life history. Some computer models incorporate data about the relationship between body composition and energy utilization and simulate real situations quite accurately, predicting how much adipose tissue is appropriate for birds engaged in certain activities under certain conditions (Witter and Cuthill, 1993; Pennycuik and Battley, 2003). But direct measurements of many species in the wild

show that there is often quite a bit of variation in fatness among members of the same species at the same times of year, which cannot easily be linked to habits or the ecological situation in which they live.

Polar bears are top carnivores living in the Arctic, where the climate is not only harsh, but extremely variable from time to time and place to place. These bears are among the very few large carnivores to have huge home ranges but no proper territories. They travel long distances between areas where ice conditions make seal hunting feasible, eating large but highly irregular meals. Moderate levels of obesity seem to be essential to such habits. A sample of young adult bears studied in the Canadian Arctic in early November, when the sea-ice was just beginning to freeze over and seal hunting was again becoming efficient, were between 10 and 21% dissectible fat, which amounted to 73 kg of adipose tissue for the largest bear whose total body mass was over 400 kg. Every year a few individuals, adults as well as newly weaned juveniles, are found in a severely emaciated condition, sometimes attributable to injury, but often from failure to catch seals or find carrion. Their superficial adipose tissue, which over the rump might be more than 10 cm thick in a successful hunter, has shrunk to a flimsy sheet of watery tissue. Their muscles are wasted, so the hips are narrow and the legs thin, and at first glance, they look more like a dog than a bear.

Average fatness can be very different in different localities (and probably also from year to year, though there is less information on this topic), even for wild animals of the same species. For example, the common red fox is usually lean where food is available regularly but predators abound, even when, as now often happens, it frequents towns and eats the remains of people's fatty meals. Populations living in Scandinavia and parts of Canada, where the food supply is very unpredictable, and predators and potential competitors are scarce, are substantially fatter than those elsewhere in Europe.

Birds that are fat for only part of the year may have habits that reduce the risks associated with being heavy. They may live and feed in flocks or herds where the "safety in numbers" principle applies, or spend time only in places where predators are few or absent. Small birds such as great tits that feed only by daylight become measurably heavier toward evening and lose weight during the hours of darkness, especially on long, cold nights. How much fat they carry from day to day correlates with the likelihood of obtaining food, which depends on both the presence of suitable prey, and being senior enough in the "pecking" order to get sufficient access to it, and on the prevalence of predators. Great tits in Britain became significantly heavier when their principal predator, the sparrow-hawk, disappeared in the late 1950s and 1960s, as a result of poisoning from agricultural insecticides. When improved farming practices allowed sparrow-hawks to reestablish themselves in western Britain in the 1970s, the mean body mass of great tits declined, though that of wrens, a species rarely caught by hawks, remained unchanged.

Migration

In contrast to walking, running and swimming, the muscle power required to stay airborne by active flapping flight

increases disproportionately with increasing body mass. Other factors being equal, smaller birds can generate substantially more power than is needed to keep airborne, so they can carry proportionately more fuel, up to 50% of the body mass if necessary. Larger wings make flying energetically more efficient, so the longest nonstop journeys are undertaken by medium-sized birds, such as sandpipers, knots, turnstones, curlews, and godwits of body mass around 100–800 g (Pennycuik and Battley, 2003).

Small birds of body mass around 100 g that set out with adipose tissue triacylglycerols amounting to 100% of lean tissue mass (i.e., half the body mass is fuel) can fly for 3–4 days nonstop or 3000–4000 km (depending greatly on wind direction and other weather conditions). Flying time can be prolonged by slowing down, or shortened by speeding up or by flying into a headwind. In general, larger birds can fly faster, and so get there sooner, but because they can carry less fuel, they often cannot go as far as medium-sized birds. Birds with a lean body mass of around 100 g lose about 0.7% of the body mass per hour while migrating, but larger birds of around 500 g flying similarly loaded lose 1–1.5% h⁻¹.

The rate of energy expenditure decreases as the birds become lighter through oxidization of fat. As they set out fully loaded, each gram of triacylglycerols takes them less than half as far as at the end of their journey, when their fuel is almost exhausted, because flying with half the body mass as fat uses three times as much muscle power as flying on “empty.” A bird that sets out with half its total body mass as fuel and flies to exhaustion uses 40% more energy for the whole journey than one that sets out with a fuel load of 10% of the body mass, flies as far as it can, stops to feed, and continues on the next lap, repeating the cycle until it reaches its destination. Such a journey is slower because even with unlimited food, birds cannot fatten faster than about 10% of the body mass per day, usually nearer 3–6% day⁻¹. So increasing the body mass by 25% takes at least a week, 3–4 weeks to accumulate maximal fuel reserves.

The amount of fuel a large bird can carry is usually limiting, and most journeys begin with a full load and end with little to spare. Whooper swans (*Cygnus cygnus*) that fly between north-west Scotland and their breeding grounds in central Iceland are among the largest of all migratory birds. The swans set out with adipose tissue triacylglycerols amounting to about 20–25% of their lean body mass, the largest load they can take off with. If they encounter bad weather or adverse winds, they settle on the sea and wait, sometimes for 30 h or more, until travelling conditions improve enough to continue their journey.

Hibernation

Hibernation and its hot weather equivalent, aestivation, are periods of inactivity and seclusion, usually accompanied by cooler than normal body temperature, which enable animals to pass through seasons when food is scarce or inaccessible. Hibernation was among the first physiological states in which adipose tissue of wild mammals, reptiles, and amphibians was studied thoroughly. Hibernators depend on their fat reserves while cold and to fuel rewarming but reclaiming the stores is not as straightforward as it first seemed.

The enzymatic processes involved in fasting and starvation are essentially similar to those of slow exercise, but there is a critical difference: during exercise, the body is warm, often slightly warmer than when sedentary, but in hibernation, the body temperature is low, sometimes falling by 35 °C to close to 0 °C. The fatty acid composition of triacylglycerols is largely irrelevant to their role as fuel when animals are warm, but it is crucial for their use during hibernation because enzymes do not work on solidified fats.

Experiments on captive chipmunks (*Eutamias amoenus*) and golden-mantle ground squirrels (*Spermophilus lateralis*) show that they enter hibernation more readily, remain cooler for longer and are better able to survive long winters when plenty of polyunsaturated lipids are included in their diet during the weeks preceding hibernation than when they are fed on saturated fats of similar calorific value. Unsaturated fatty acids may lower the melting point of the triacylglycerols and the membrane phospholipids, enabling them to remain more fluid, and hence retain their proper affinity for carrier molecules and enzymes, at cooler temperatures. The chemical composition of the storage lipids, together with other aspects of adipose tissue, is thus adapted to the physical conditions and its role in whole-body metabolism (Frank and Storey, 1995; Frank *et al.*, 2008).

Squirrels obtain many such unsaturated fatty acids from the seeds and other plant parts that they eat. Hibernation is an active, physiologically controlled process, and especially in mammals, metabolic preparations can be identified days or weeks before the animal actually allows its body to cool. As the weather becomes cooler and the days shorten in autumn, squirrels, and other hibernatory rodents actively seek nuts and other foods that contain these lipids. The woodchuck or marmot (*Marmota flaviventris*) selectively retains linoleic acid (C18:2) before hibernation: the saturated fatty acids are released and oxidized by the muscles, liver, etc. while the animal is warm and active, but the polyunsaturates remain in the adipose tissue, for use when the body is cold. Like other mammals, the squirrels cannot add more than one double bond to most kinds of long chain fatty acids, so they depend on the increased availability in autumn of seeds rich in polyunsaturated lipids. Failure of a seed crop could prevent successful hibernation and thus lead to death from cold or starvation, even if plenty of other foods were available. Analysis of biopsies of gonadal and inguinal adipose tissue from alpine marmots (*Marmota marmota*) throughout the year indicate that selective release of certain fatty acids allows active regulation of the composition of storage triacylglycerols (Cochet *et al.*, 1999). The storage lipids remain fluid during deep hibernation and in the euthermic state by maintaining a high proportion of monounsaturates, both by retention of those from the diet and, if necessary, by synthesis.

Sleeping undisturbed in a cool, secluded place uses storage materials only very slowly: small tortoises may lose less than 5%, and rarely lose over 15%, of the body mass during 5 months of hibernation at about 5 °C. Many reptiles and amphibians emerge from hibernation with a surprisingly large proportion of their lipid reserves still remaining and regain what they lost over the winter in a few weeks of feeding. These stores are often important for fuelling mating and

egg production. The less lipid a hibernator uses during the winter, the more it has left to fuel breeding the following spring.

Reproduction

The formation of large, yolky eggs that nourish the embryo until it is at an advanced stage of development is a very ancient means of reproduction among vertebrates. Most sharks, skates and rays, whose ancestors were abundant in Devonian seas 400 million years ago, produce such eggs, which hatch into miniatures of the adults, capable of feeding for themselves.

One third of the fresh mass of the yolk of birds' eggs is storage fats, a proportion that may represent the maximum that can form a stable emulsion, holding the lipids in a state that the embryo or its mother can handle. The relative size of the yolk and the "white" part of eggs differs greatly between species, being lowest in species that feed their young on the nest for some time after hatching, such as pelicans (17% of the mass of the egg), gannets (18%), and crows (19%). Yolk content is highest in species whose relatively large eggs hatch to produce large, mature chicks that can walk well and feed themselves. The yolkiest eggs are those of kiwis (65%), megapodes, also known as brush turkeys or mound-builders (over 51%), ducks (40%) and, of course, species of the order Galliformes, which includes turkeys, peafowl, pheasants, guinea-fowl, quail, and domestic poultry.

In developing domestic chickens, the cells lining the gut start "eating" droplets of yolk around the twelfth day of incubation, and pass its lipids into the blood as lipoproteins. At the same time, the adipose tissue matures and starts to produce lipoprotein lipase in large quantities, enabling it to take up the yolk lipids. Both the number and the mean size of adipocytes increase until at least the nineteenth day of incubation, and continue after hatching on the twenty-first day. The adipose tissue serves as more than just a temporary store: its adipocytes and the lipoprotein lipase they produce discriminate between triacylglycerols of different fatty acid composition, and thereby "ration" the embryo's irreplaceable lipid provisions to ensure normal development (Speake *et al.*, 1998; Speake and Wood, 2005).

Lipids are the main agents of transfer of energy from mother to offspring in most vertebrates and many other kinds of animals, including insects. Mammals are somewhat unusual in that their eggs are very small and contain almost no yolk because soon after fertilization they attach themselves to the lining of the uterus, forming a placenta, through which the embryo obtains all the nutrients it needs. Lipids cross the placenta and enter the fetal blood but most seem to be deployed in structural roles, particularly the formation of membranes of the brain and nervous system, rather than being broken down for energy production. The situation changes abruptly at birth, when the neonate starts to suckle. The milk of most mammals is rich in triacylglycerols but contains only small quantities of carbohydrate as lactose. During suckling, carbohydrates and lipids almost swap the roles they had in the fetus: suckling mammals convert lactose into glucose, most of which is incorporated into proteins or other structural materials and lipids become the main source of fuel.

The lactation habit has the enormous advantage that it emancipates mammals from the limitation of breeding only

where and when suitable food is available for the young, and permits rapid growth of the neonate (Pond, 2011). Lactation combined with storage is the main reason for the rarity of long-distance migration in relation to reproduction among mammals compared to birds and other vertebrates.

For some species, food supplies are too erratic, or obtaining them requires too many long absences from the nest, for lactation to be fuelled just by eating more. Milk production has to draw on the body's reserves of lipid from adipose tissue, calcium and other minerals from the skeleton and protein from it is not clear where, probably mainly muscle and liver. So many female mammals fatten during pregnancy, and deplete their adipose tissue lipids during lactation. Soon after birth, changes to hormones, their receptors and enzymes give the mammary glands preferential access to circulating lipids and act on adipose tissue, disabling its uptake of triacylglycerols from the blood and prompting fatty acid release. These changes direct fatty acids from the adipose tissue to the mammary gland, where they are incorporated into milk triacylglycerols. Although storage lipids contain only long-chain fatty acids, the enzymes of the mammary gland readily esterify medium-chain and even short-chain fatty acids into triacylglycerols. The precursors of milk of adequately fed mammals come straight from the gut without going via the adipose tissue so may include fatty acids that are never appear in storage triacylglycerols. But during fasting, the adipose tissue becomes the major source of fatty acids, so the milk triacylglycerols from starving animals always contain more long-chain fatty acids.

The composition of fatty acids in milk triacylglycerols is thus very variable in many mammals, depending on what the mother has just eaten, and how much is derived from her adipose tissue, or obtained directly from the diet. The contribution of storage lipids is important for wild animals where there are lipid-soluble pollutants such as dichlorodiphenyl-trichloroethane (widely used as an insecticide from the 1940s to the 1970s) and polychlorinated biphenyls (formerly used as components of large batteries and other electrical apparatus). Such contaminants eaten during lactation may go straight into the milk, and in fasting mothers such as bears, those that have accumulated in adipose tissue during the previous months get released with the fatty acids and so transferred into the milk. These effects can produce alarmingly high concentrations of toxins in the offsprings' tissues, permanently impairing growth and development. Lipid storage in adipose tissue is central to this breeding strategy, enabling mothers to store enough materials to synthesize milk at a high rate, and the young to take full advantage of the nutrients their mother provides during the often brief period during which they are together. Its role is enhanced in large species that live in highly variable habitats. Polar bears (Figures 4 and 5) can carry so much storage tissue around because they have no natural predators (other than humans) and hunt by stealth and skill rather than by speed and agility. The bears' massive adipose tissue enables females to separate feeding and mothering to a greater extent than is possible for almost all other warm-blooded animals, thereby equipping them to breed successfully in spite of the arctic vagaries of food supplies.

Marine mammals can afford to be fatter, at least for short periods, than terrestrial species because they do not attempt to move far or fast on land, and so are less constrained by the

mechanical limitations to fatness. There are no large terrestrial predators in the Antarctic, so seals breeding on beaches or on sea-ice can afford to suckle their young for several weeks. But those living in and around the Arctic are obliged to share their habitat with polar bears and have evolved ways of transferring lipids from mother to young at a spectacular rate. Harp seals (*Phoca groenlandica*) that breed on pack-ice throughout the Canadian and Russian Arctic are only 3% by weight lipid at birth but reach 47% lipid at weaning 13 days later. The single pup drinks an average of 3.7 kg of milk each day, gaining weight at an average rate of 2.3 kg day⁻¹. Transfer of lipid from mother to offspring gathers pace as the young matures: the lipid content of the milk increases from 36% at the start of lactation, to 57% just before weaning.

Lactation in the hooded seal (*Cystophora cristata*) which breeds on temporary ice-floes in the North Atlantic is even more compressed. The single pup weighs about 22 kg at birth, large relative to adult size, but is only slightly fatter than harp seal pups. It almost doubles its body mass to around 43 kg in only 3–5 days of suckling. Over 70% of the increase in body mass is blubber, which holds enough lipid to sustain the pup during a postweaning fast that can last several weeks. During the 4 days of lactation, the mother's body mass declines from 179 to 150 kg, over 80% of the loss being from the blubber as she synthesizes milk at 2.5–6 times the rate of other seals that have been studied, probably a record for any mammal. Such haste may be necessary to minimize the risk that mother and pup become separated by storms and currents that move ice-floes around, as well as that of predators.

Most mammals are weaned with storage tissues replete, especially carnivores and other species for which skill and experience are essential for finding food. Much of the triacylglycerols transferred to suckling seals is stored in their own blubber, and utilized during the long period between weaning and the pups becoming proficient at finding food for themselves.

Comparing Extinction Rates: Past, Present, and Future

Vânia Proença and Henrique Miguel Pereira, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal

© 2013 Elsevier Inc. All rights reserved.

Glossary

Background extinction rate The natural rate of extinction over geological time, measured from the fossil record and independent of anthropogenic influence.

Extinction rate The number or proportion of taxa becoming extinct per unit time.

Mass extinction Rare events in Earth's history when extinction rates escalated and extinction reached devastating magnitudes in a relatively short period of geological time.

Mass extinction events affected species from a wide variety of taxa and had a global impact, affecting all regions. There

were five mass extinction events in Earth history with magnitudes of 75% or more of species loss.

Species committed to extinction Species whose populations have already experienced, or will probably experience, severe population declines that compromise the viability of their genetic and demographic base and anticipate the eventual extinction.

The IUCN Red List of Threatened Species™ A list built by the International Union for Conservation of Nature (IUCN) that provides information on the global conservation status of assessed species of plants and animals.

Why to Assess and Compare Extinction Rates?

Current estimates of biodiversity range from 5 million to 30 million species (a recent estimate of *Mora et al. (2011)* suggests a value of 8.7 million terrestrial eukaryotes), but living species may represent only a small fraction, 2–4%, of all species that have ever existed on Earth (*Mace et al., 2005*). The reasons for this small fraction of remaining species include species evolving, with species giving origin to others (this is called pseudo-extinction), species becoming extinct not only due to competitive exclusion or failing to cope in their environment, but also the occurrence of discrete extinction events associated with abrupt peaks of environmental stress (*Raup, 1992; Green et al., 2011*).

Species extinction, like species origination, is a natural process in species evolution and diversification. The natural disappearance of species has occurred on a rather constant and low rate through geological time (*Raup, 1986*). This natural rate of extinction is called the background extinction rate. The background extinction rate was interrupted by five events of mass extinction (in the Ordovician, Devonian, Permian, Triassic, and Cretaceous) when extinction rates escalated and extinction reached devastating proportions of at least 75% loss of all existent species in a relatively limited time interval at the geological scale (*Barnosky et al., 2011*). Mass extinction events affected species from a wide variety of taxa and had a global impact, affecting all regions. Biodiversity recovery after each mass extinction was a slow and long process as new species evolved during millions of years (*Kirchner and Weil, 2000*).

Current and recent past extinction rates, measured from records of species loss from the last few centuries, and future extinctions rates, estimated using scenarios and modeling approaches, are much higher than the background extinction rate (*Figure 1*), or in other words than the expected natural rate of species loss (*Mace et al., 2005; Pereira et al., 2010a*). This is very worrying because species extinction is a definitive and irreversible form of biodiversity loss. The increase of extinction rates is directly or indirectly driven by human activities and may have negative consequences for humankind. The

impoverishment of natural communities and the disruption of ecosystem functioning are caused by several drivers, in particular habitat change, climate change, invasive species, pollution, and unsustainable use of biological resources (*MA, 2005; SCBD, 2010*). These drivers act together, creating combined pressures over ecosystems and showing complex dynamics at different temporal and spatial scales, which pose huge challenges to their understanding and control (*Pereira et al., 2010a*).

The comparison between past extinction rates, estimated from the fossil record before human-era disturbances, and anthropogenic extinction rates, derived from documented extinctions and from quantitative models, is a way of discriminating human-induced extinction from natural extinctions. This allows us to put into perspective the extent of the modern biodiversity crisis and to evaluate the severity of human impacts on biodiversity. This information is essential for the prioritization and design of conservation measures that may reduce extinctions and prevent harmful and severe consequences for natural systems and humankind.

Metrics of Extinction

Metrics of Magnitude and Rate

Extinction can be measured using different metrics (*Table 1*) that can be classified in measures of magnitude or measures of rate. The first includes the number or proportion of extinctions and the latter correspond to the number or percentage of extinctions over a time interval. Using a measure of magnitude or rate depends on the purpose of the assessment. Measures of magnitude provide information on the extent of the extinction. The proportion of extinctions normalizes the number of extinctions over the total number of species in the species pool, thus controlling the effect of sample size (i.e., the species pool). However, this metric, like other measures of magnitude, lacks information on the duration of the time interval along which extinctions occurred, being therefore less suitable for comparing past and modern extinctions due to the disparity in

Figure 1 Past, recent, and future extinction rates. Past extinction is represented by the extinction rate of mammals in the Cenozoic fossil record (upper bound from Barnosky *et al.* (2011) and lower bound from Foote and Raup (1996)); recent extinction is represented by the extinction rate of mammals (upper bound), birds, and amphibians (lower bound) in the twentieth century, using documented extinctions (Mace *et al.*, 2005); future extinction is represented by projections of species committed to extinction in the twenty-first century, according to different global scenarios: vascular plants (Malcolm *et al.*, 2006; van Vuuren *et al.*, 2006), plants and animals (Thomas *et al.*, 2004), birds (Jetz *et al.*, 2007; Sekercioglu *et al.*, 2008), and lizards (Sinervo *et al.*, 2010). Extinction rates driven by land-use change or by climate change are discriminated when possible. Modified from Pereira HM, Belnap J, Brummitt N, *et al.* (2010b) Global biodiversity monitoring. *Frontiers in Ecology and the Environment* 8: 459–460, and Pereira HM, Leadley PW, Proença V, *et al.* (2010a) Scenarios for global biodiversity in the 21st century. *Science* 330: 1496–1501.

Table 1 Extinction metrics and their definition

Extinction metric	Definition
Number of extinctions	E
Proportion of extinctions	E/S
Van Valen metric ^a	$E/(S - E/2 - O/2)$
Total extinction rate	E/t
E/MSY	
Proportional extinction rate (linear model)	(E/S)/t
Proportional extinction rate (exponential model ^b)	$-\ln(1 - (E/S))/t$
Van Valen metric per unit of time	$(E/(S - E/2 - O/2))/t$

^aThe denominator $(S - E/2 - O/2)$ in the Van Valen metric is an estimate of standing diversity. It corresponds to the estimated diversity at the midpoint of a time interval, assuming a linear change in diversity along the interval (see Foote, 1994).

^bFor a given time interval the proportion of species going extinct is $E/S = 1 - e^{-\lambda t}$, where $\lambda = E/MSY$.

E, number of extinctions; S, total diversity in the time interval; O, number of originations; t, time interval, conventionally expressed in million years.

the length of the respective time intervals. Extinction rates constitute a more appropriate metric to compare background extinction with current extinction because extinction is expressed per time unit, thus informing on the pace of species loss. However, extinction rates may be misleading because the

normalization by time assumes that extinctions are distributed evenly along the time interval, which might not be true (Foote, 1994).

Measuring Extinction in E/MSY Units

The E/MSY metric, that is, extinctions per million species-years, has been widely adopted to measure extinction rates (Pimm *et al.*, 1995; Mace *et al.*, 2005). It is a proportional extinction rate measure (Table 1), having the advantage of normalizing the rate of extinction both by time and size of the species pool, allowing the comparison of extinction rates between different periods of time and between species pools of different sizes. For instance, studies suggest an average background extinction rate of terrestrial mammals of 0.4 E/MSY (Foote and Raup, 1996) to 1.8 E/MSY (Barnosky *et al.*, 2011). A value of 1 E/MSY can be interpreted as one extinction per thousand species per thousand years. Hence, when evaluating current extinction rates, a natural rate of extinction would be, for example, one species extinct in a total of 10,000 species during a time interval of 100 years.

There are several approaches for calculating E/MSY (Table 1): the linear model, the exponential model (also known as per capita extinction rate), and the Van Valen metric

per unit time. The linear model assumes that the proportion of extinctions, E/S , increases linearly with time. This assumption tends to be violated for long time intervals or very high extinction rates (Foote, 1994). Therefore, extinction rate estimates using the linear model are sensitive to the size of the time interval over which they are calculated, tending to decrease as the time interval increases (Foote, 1994; Regan *et al.*, 2001).

A better model of the process of extinction is the exponential model (Foote, 2000). It assumes that the lifetime of each species is given by an exponential distribution. The parameter of the exponential distribution is the per capita rate of extinction and corresponds to the value of E/MSY . Therefore, the inverse of E/MSY is the mean life expectancy of a species, which for a value of 1 E/MSY corresponds to 1 million years. The exponential model is particularly appropriate to compare different estimates of future extinction rates, as several studies report values that are extremely high (Pereira *et al.*, 2010a), which would lead to the saturation of the linear model (i.e., extrapolations of the extinction rates for the future could lead to magnitudes greater than 100% extinction).

Another alternative to the linear model is the Van Valen metric (Foote, 1994). It accounts for both speciation and extinction events (Foote, 1994), and therefore it is commonly used in paleontological studies. The exponential model can also be modified to account for both speciation and extinction (Foote, 2000).

Projected Extinction and Realized Extinction

Although past and recent extinctions refer to the disappearance of a species on the death of its last surviving individual, most projections of future extinction are based on estimates of species committed to extinction. Species committed to extinction are those whose populations have already experienced, or will probably experience, severe population declines that compromise the viability of their genetic and demographic base and anticipate the eventual extinction (Heywood *et al.*, 1994). The time needed for extinction is not certain (Sala *et al.*, 2005; Leadley *et al.*, 2010), because the time lag between impacts, population decline and realized extinction may range from decades to millennia, and in some cases declining trends may even be reverted if measures are taken to halt the causes of endangerment and restore populations.

Currently, 3663 species, from a total of 56,135 species of vertebrates, insects, mollusks, and plants that have already been assessed by the International Union for Conservation of Nature (IUCN) Red List are considered as critically endangered (IUCN, 2011), which means that these species are facing an extremely high risk of extinction in the wild, and will be committed to extinction if the present conditions are maintained or worsened (Heywood *et al.*, 1994). Some of these critically endangered species are species “possibly extinct” (Butchart *et al.*, 2006). “Possibly extinct” species are species that are likely to be extinct because they have not been seen for many years, but for which there is still a small chance that they may be extant (Butchart *et al.*, 2006). These species will only be considered as extinct after adequate efforts to prove their extinction in the wild (Butchart *et al.*, 2006).

Projections of future extinction may include the species that are currently committed to extinction (Barnosky *et al.*, 2011) or the species that might be committed to extinction in the future (Pereira *et al.*, 2010a). The number of species committed to extinction in the future may be assessed by using trends of degradation of species conservation status to extrapolate how many species will be extinct or become critically endangered in the future, or by estimating how many species will become endangered due to projected trends in drivers of change (*see* Future Extinction).

Overall, extinction rates in the future will probably be lower than what is suggested by projected extinction rates because not all species committed to extinction will become extinct. However, current extinction rates, based on recent extinction data, correspond to conservative estimates because some “possibly extinct” species will eventually be classified as extinct.

Present Extinction

Human-Induced Extinction Rates

Human-induced extinctions followed the growth and expansion of human populations across the globe. The extinction of megafauna species in the late Pleistocene (ca. 50,000 BP–12,000 BP) was at least partly a consequence of over-exploitation and habitat change, although climate change may have also contributed to extinctions, especially in the northern hemisphere (Barnosky *et al.*, 2004). Human migration through land and sea lead humans to regions where biota had evolved without human disturbance. The coincidence between records of first human arrival and records of widespread extinction suggest that humans were responsible for or prompted species disappearance (Steadman, 1995). Islands provide a paradigmatic example: after the first human arrivals, 1500–2000 years ago, between 70 and 90 endemic birds were extinct in the Hawaiian archipelago, in an estimated pool of about 150 species, and 40% of large mammals were extinct in Madagascar (Pimm *et al.*, 2006). Overall, at the global level around one-third of autochthonous mammals were extinct from oceanic islands and oceanic-like islands, such as the Mediterranean islands (Alcover *et al.*, 1998).

The IUCN Red List (www.iucnredlist.org) includes more than 800 records of extinctions since the 1500s, including nearly 200 extinctions of birds and mammals (Baillie *et al.*, 2004; Mace *et al.*, 2005). Most records refer to realized extinctions and less than 10% refer to extinctions in the wild (i.e., species that disappeared from their natural habitat but still survive in captivity). Considering mammals, birds and amphibians all together, there were about 100 documented extinctions since the start of the twentieth century (Mace *et al.*, 2005), in a total pool of nearly 21,000 described species, which corresponds to an extinction rate of 48 E/MSY , which is 30–120 times greater than the background extinction rate of 0.4–1.8 E/MSY for mammals. If possibly extinct species are included, then the number of extinctions rises to 215, resulting in an extinction rate of 102 E/MSY (Mace *et al.*, 2005).

There are several sources of uncertainty that affect the assessment of current extinction magnitudes and rates. A basic

problem is that we do not know with an adequate certainty how many species exist in the world today and we only know a very small fraction of species. In addition, systematic species description only started during the eighteenth century and only about 1.7 million species have been described up to the present day (IUCN, 2011). That means that many taxa may have become extinct, or will become extinct, before being described. Another problem is that existing data are biased toward terrestrial vertebrates, which are better known and monitored than all other taxa but represent only around 2% of described species (Mace *et al.*, 2005). Moreover, several species are rare or have secretive habits, which constrains the assessment of their current status, including extinction. Finally, the time lag between impacts and extinction also limits an accurate estimation of extinction rates.

Therefore, estimates of the magnitude of contemporary extinctions, derived from documented extinctions, are very conservative, because only a small fraction of species has been described and monitored. In addition, estimates of current extinction rates are probably very conservative as well, since only realized extinctions are considered (Baillie *et al.*, 2004; Pimm *et al.*, 2006). Still, estimates of current extinction rates are already very high when compared with background extinction rates (Figure 1). This value will probably rise in the near future due to the continuous degradation of species conservation status, as revealed by the Red List Index (RLI) (Figure 2), which measures trends of species extinction risk across time (Hilton-Taylor *et al.*, 2009; Butchart *et al.*, 2010; Hoffmann *et al.*, 2010).

Figure 2 Changes in the Red List Index (RLI) for the period of 1980–2010, for birds, mammals, and amphibians. The RLI varies between 0 and 1: 1 corresponds to all species having a conservation status of Least Concern, and 0 corresponds to all species being extinct. A decrease in the RLI indicates that species' conservation status are worsening. Shaded areas correspond to 95% confidence intervals. Reproduced from Figure 3A. Trends in the Red List Index (RLI) for the world's birds, mammals and amphibians in Hoffmann M, Hilton-Taylor C, Angulo A, *et al.* (2010) The impact of conservation on the status of the World's vertebrates. *Science* 330: 1503–1509.

Species extinction rates can also be estimated indirectly using data on drivers of species extinction, such as habitat loss. For example, species extinction along time after habitat fragmentation can be modeled by assessing species loss in habitat fragments of different size and age since fragmentation (for more details see Pimm and Brooks (1999)). These modeling studies tend to deliver higher rates of extinction than the conservative approach, on the range of three to four orders of magnitude higher than a background extinction rate of 1 E/MSY (Pimm and Brooks, 1999). True values of current extinction are probably found between the estimates delivered by both approaches, but nevertheless they will always be much higher than the background extinction rate.

Patterns of Modern Extinction

Patterns of contemporary extinction are not homogenous across the globe and across species groups. Islands have been the stage of most documented extinctions so far (Figure 3), encompassing 62% of mammal extinctions, 88% of bird extinctions, 54% of amphibian extinctions, and 68% of mollusc extinctions (Baillie *et al.*, 2004). The main causes of extinction were habitat loss, the introduction of invasive species, which includes the introduction of predators, competitors, and pathogens, and overexploitation (Baillie *et al.*, 2004). In the case of large birds and mammals, overexploitation and direct persecution were important causes of extinction. Species extinction in continents has become more frequent during the past century (Figure 3). Habitat change has been the main driver of species extinction in continental areas, but climate change is also becoming increasingly important (Leadley *et al.*, 2010).

The extinction record of terrestrial species is still very incomplete; even so this is the group for which present conservation status and recent extinctions are better studied. In contrast, the conservation status of freshwater and marine

Figure 3 Bird extinctions on islands (black) and continents (gray) since 1500 AD. Reproduced from Baillie JEM, Hilton-Taylor C, and Stuart SN (2004) *2004 IUCN Red List of Threatened Species. A Global Species Assessment*. Gland: IUCN.

species is still a major unknown. There are still few records of global extinction in the marine realm, which may be due to the lack of data and adequate detection methods (Dulvy *et al.*, 2003; Baillie *et al.*, 2004). Marine species appear to be as vulnerable to human action as terrestrial species, and given the long history of human use of oceans, especially in coastal areas, one might expect a higher number of extinctions than the extinctions documented (Dulvy *et al.*, 2003). Over-exploitation has been identified as the main cause of extinction of local populations, and it may cause the collapse of several world fisheries in the next decades (Worm *et al.*, 2009). Habitat destruction, pollution, and climate change are also important drivers, with severe impacts in coastal regions and in coral reefs (Dulvy *et al.*, 2003; Leadley *et al.*, 2010).

Species extinctions in freshwater systems were best documented in the USA (Baillie *et al.*, 2004). Data reveal a high magnitude of extinction, with 105 documented extinctions due to habitat destruction, pollution, and invasive alien species (Baillie *et al.*, 2004). In addition, data of freshwater fishes conservation status on the IUCN Red List indicate that more than 50% of species in the Mediterranean and Madagascar and nearly 50% of species in Europe may be threatened (Darwall *et al.*, 2009). These values are alarming, because they suggest that freshwater species could be even more threatened than terrestrial species.

A characteristic shared by many extinct species and seriously threatened species is their low total abundance, that is, a relatively small number of individuals at the global level (Pimm and Jenkins, 2010). This includes species that have limited distribution ranges and species that have large distribution ranges but are rare. In the first case, examples include the endemic species on islands, which could be rare or have high local population densities, but always have a low global abundance due to their limited distribution, and also endemic species in continental areas whose distribution is also limited. The second case includes species with large distribution ranges but with low densities and therefore with a low total abundance, this is the case with top predators, such as large carnivores.

When analyzing regional patterns of extinction, the regions that concentrate a high number of endemics are also the ones where species loss is more probable. This is the case of the biodiversity hotspots that concentrate a high diversity of endemics, and which were exposed to extensive habitat change and continue to face a severe threat of further habitat loss (Myers *et al.*, 2000; Brooks *et al.*, 2002). Extinctions may be less pronounced in regions with few endemics even when the level of impacts is considerable, such as in eastern North America, where intense deforestation since the 1600s caused the extinction of four species only from a total of 162 forest species (Pimm and Jenkins, 2010).

Future Extinction

Projecting Extinction Rates

Future extinction rates will depend on several factors, including demographic and socio-economical variables, trends in drivers of environmental change (e.g., climate change) and

ecosystems and species responses to drivers of change. Research approaches to estimate future extinction rates generally include three main components: socio-economic scenarios, models to project the future state of environmental change drivers, and models to project ecosystems and species response to those drivers (Pereira *et al.*, 2010a).

Socio-economic scenarios are used to characterize changes in demographic and socio-economic variables, such as population growth, fossil fuel use, or implementation of environmental policies. Demographic and socio-economic variables act like indirect drivers of biodiversity change affecting the trajectory of environmental change drivers (e.g., climate change and land use change), which will have a direct effect on species and ecosystems. Finally, projections on the future levels of direct drivers are used to assess ecosystems and species responses to environmental changes. The response of species to drivers of change is usually estimated using phenomenological models or process-based models.

Phenomenological models are built on empirical relationships between environmental variables, such as area of natural habitat or precipitation, and biodiversity metrics, such as species richness or presence/absence of particular species. Examples of phenomenological models to assess species extinction include species–area relationships, niche-based models, and dose-response models (Leadley *et al.*, 2010). Species–area relationships are based on the known correlation between habitat area and species richness (Sala *et al.*, 2005; van Vuuren *et al.*, 2006). These models derive species extinction from the extent of predicted habitat loss. Niche-based models (or species distribution models) are based on the effect of environmental variables, namely climatic variables, on species distribution. These models use species' current distributions to define their environmental niche, or their "climate envelope" in the case of climatic variables (Thuiller *et al.*, 2008). Changes in environmental conditions will have effects on species distribution ranges, thus the future distribution of a species is estimated by combining current environmental niches with future environmental conditions. Species extinction may occur if species fail to change their distribution range in order to adapt to environmental changes, for example, due to limitations to migration, such as physical barriers or species inability to migrate. Dose-response models establish the relations between the intensity of a global change driver, which is the "dose", and the species responses (Alkemade *et al.*, 2009). An example is the decrease in plant species richness with increasing levels of nitrogen deposition.

Process-based models simulate biological processes such as population growth or mechanisms such as ecophysiological responses (e.g., changes in climatic variables affecting rates of photosynthesis, respiration and evapotranspiration in plants, or affecting demography of animal populations) to mimic species or population responses to environmental changes (Thuiller *et al.*, 2008).

Future Extinction Rates

Future global extinction rates have been projected for different taxa. Existing studies are mainly directed at terrestrial species (Figure 1, Table 2) and very few address the marine and

freshwater realms (Pereira *et al.*, 2010a). Studies on terrestrial species are focused on two main drivers: land-use change and climate change. Each study uses a set of interconnected scenarios, including socio-economic, climatic and land-use change scenarios, to model extinction rates and bound estimates between potential best- and worst-case scenarios (Figure 1, Table 2). All projected extinction rates are much higher than the background extinction rate (fossil record), with several studies projecting species becoming committed to extinction at rates as high as thousands of extinctions per million species-years (Table 2, Figure 1). Even best-case scenarios, that is, the lower bounds of the intervals of variation of projected extinction rates, are projected to be above recent extinction rates in most studies (Figure 1).

All studies in Table 2 except Sinervo *et al.* (2010) use phenomenological models to project the number of species committed to extinction. These studies estimate extinctions based on habitat loss due to land-use changes and/or climatic changes (e.g., van Vuuren *et al.*, 2006), or due to shifts in species ranges driven by climatic changes (e.g., Thomas *et al.*, 2004). One study, Sinervo *et al.*, 2010, uses a physiological model (process-based model) to project the number of species committed to extinction given climatic changes. The authors project lizard extinction by modeling species thermal tolerance and adapting behavior in the face of increasing environmental temperatures.

Two studies, by van Vuuren *et al.* (2006) and Jetz *et al.* (2007), analyze the separate and combined effects of land-use change and climate change on the rate of species extinction of plants and birds, respectively. Both studies predict that land-use change will cause more extinctions than climate change during the twenty-first century. However, the effects of those two drivers will not be uniform across the globe: climate change will mostly affect natural communities in high latitudes and elevated regions, whereas land-use change will be the prevailing driver of species loss in temperate and tropical latitudes, where a higher diversity of endemic and specialist species is also found.

Global studies on future extinction risk of marine species are less common. Cheung *et al.* (2009) investigated the effect of climate change on distribution ranges of marine species, fish and invertebrates, and predicted patterns of local extinction and invasion. Results point to numerous events of local extinction particularly in the subpolar regions, tropics and semi-enclosed seas, and invasions in the Arctic and the Southern ocean. Species turnover will occur at a global scale with potential deleterious effects for ecosystem functioning. The authors found a global average local extinction rate of 3% by 2040–2060 of the initial species richness in 2001–2005. Despite being local extinction values, they are below most projected global extinction rates for terrestrial species. This may be partially explained by a higher dispersal ability of marine species in relation to terrestrial species.

The future extinction risk of freshwater species has been addressed in a study on the consequences of changes in river discharge, due to a decline in run-off caused by climate change and water withdrawal from human activities, in selected river basins across the globe (Xenopoulos *et al.*, 2005). Species extinction was determined at the basin scale and results suggest that 15% of the world's rivers may have more than 20% of

their fish species committed to extinction during the next century.

Uncertainty in Projected Extinction Rates

The large variation in projected extinction rates, within studies and among studies, raises questions about their accuracy and suitability for comparison with past and recent rates. Pereira *et al.* (2010a) identify three main sources of uncertainty in projected extinction rates: (1) variation in the intensity of the drivers of change, (2) lack of knowledge on species ecology and species response to drivers, and (3) differences in modeling approaches and in model sensitivity.

The first factor (1) underlies much of the variation within studies. Studies test different scenarios, characterized by different degrees of land-use or climate change, to encompass a variety of possible futures and assess the effects of each scenario on biodiversity.

The second factor (2) is also a significant cause of variation in projected extinction rates within studies. Species may be able to adapt or show different levels of tolerance to changes. When the level of adaptation is weakly understood, the option is to test several alternatives that represent species responses. For example, Thomas *et al.* (2004) include species ability to migrate in their model and found a large difference in projected extinction depending on that characteristic (38% species loss with unlimited migration vs. 58% species loss with no migration).

The last factor (3) should explain most of the variation between studies, and it is related with differences in the modeling approaches used by the studies and on the criteria used to define species extinction. For example, while Jetz *et al.* (2007) estimate extinctions based on the number of species projected to lose 100% of their initial habitat from biome changes caused by climate change and land-use change, Thomas *et al.* (2004) use niche-based models to project decreases in species ranges caused by climate change and estimated extinctions based on species–area relationships.

Reducing uncertainty in projected extinction rates is critical for a more accurate comparison of extinction rates and to better inform decision makers. The evaluation of model projections, by validating models against data and using indicators to compare models outputs, and the harmonization of modeling methods are essential steps toward this objective (Pereira *et al.*, 2010a). Also important is the development of models, particularly process-based models, that integrate the effects of a broader range of drivers, and which capture the feedback of the biodiversity changes to the human system and the drivers of environmental change.

Comparing Past, Present, and Future Extinction Rates

Are We Driving the Sixth Mass Extinction?

Recent extinction rates are up to two orders of magnitude higher than the background extinction rate and future extinction rates are projected to be at least as high as current rates and likely one or two orders of magnitude higher. A

relevant question is whether mankind is driving a new mass extinction. Although past extinction rates provide a useful benchmark to evaluate the extent and severity of modern extinction rates, events of mass extinction are usually defined as the loss of at least 75% of species in a relatively short period in geological time, which provides a measure of magnitude but it is elusive regarding duration. Mass extinction events may have occurred in less than a year, along thousands of years or along millions of years (Raup, 1992; Barnosky *et al.*, 2011).

A way of dealing with this limitation is to compare simultaneously measures of rate and magnitude (Barnosky *et al.*, 2011). With this approach it is possible to assess if current rates of extinction may lead to a magnitude of extinction identical to the magnitude of past mass extinctions. Barnosky *et al.* (2011) calculated the range of variation of possible extinction rates for each event of mass extinction, using data on their magnitude and the interval of their possible duration, and then compared those values with modern rates of extinction of vertebrates considering not only species extinct in the past 500 years, but also all critically endangered and all threatened species (critically endangered, endangered and vulnerable species) that could become potentially extinct in the near future (Figure 4). Current rates of observed extinctions are already above the rates associated with all mass extinction events but the Cretaceous mass extinction. However, with the

exception of the Cretaceous event that may have spanned from a period of less than a year to 2.5 Myr, all past events spanned for periods much larger than 500 years. If a hypothetical and fixed period of 500 years is set for comparison purposes, then modern rates of extinction will be slower than past rates, but will become dangerously similar to the rates of past mass extinctions if the (hypothetical) extinction of currently threatened species is also considered in that time span.

It is worth noting that future extinction rates derived from scenarios (Figure 1) are in many cases higher than hypothetical extinction rates calculated considering threatened species as inevitably extinct in a period of 500 years (Figure 4).

Following a different approach, one can also ask if modern extinction rates may lead, and in how much time, to a magnitude of 75% species loss. This question may be answered by testing different rates of extinction based on hypothetical assumptions, namely by assuming the loss of all threatened species or of just critically endangered species, in a period of 100 years or of 500 years, and then using those extinction rates to determine the interval of time needed to reach a magnitude of 75% loss. According to Barnosky *et al.* (2011) reaching 75% of (mammals, birds, and amphibians) species loss may take from a few centuries in a worst-case scenario, if all threatened species are lost in the next century, to about ten millennia, if only critically endangered species become extinct in the next five centuries.

Figure 4 Extinction rate vs. extinction magnitude of past mass extinction events and of modern extinction (past 500 years). Vertical lines on the right illustrate the range of extinction rates for each event of mass extinction that would result in the magnitude associated with each event. The range of extinction rates varies accordingly with the interval of possible duration of each event. Each colored dot on the right represents the extinction rates associated with past events of mass extinction if they have occurred (hypothetically) over only 500 years. Dots and lines on the left represent modern extinction rates computed for a period of 500 years for vertebrates, using data from already extinct species (light yellow) and of species committed to extinction: critically endangered species (dark yellow) and all 'threatened' species (orange). If all threatened (TH) species became extinct in 100 years and that rate was maintained in the future, a magnitude of 75% species loss would be reached within 240–540 years. A similar scenario using the rate of critically endangered (CR) species yields an estimate of 890–2270 years. Reproduced from Figure 3. Extinction rate versus extinction magnitude in Barnosky AD, Matzke N, Tomiya S, *et al.* (2011) Has the Earth's sixth mass extinction already arrived? *Nature* 471: 51–57, with permission from Nature.

Caveats to Comparison

Differences in criteria and in the quality of the data used to assess past, present, and future extinction rates are major sources of uncertainty limiting their comparison.

Estimates of past extinction are based on the fossil record, which is a very restricted sample of past diversity. Only a very limited (but still impressive) fraction of species left a trace of their existence in the fossil record. Overall around a quarter of a million species have been identified from a total of tens of millions of well-preserved fossils (Raup, 1992). Near-shore aquatic species are among the most common, because sediments in riverbeds, lakebeds, and in the seabed tend to provide a good medium for fossil preservation (Raup, 1992; Barnosky *et al.*, 2011). In addition, organisms with hard body parts, such as bivalves, fossilize better than soft-body organisms, such as insects. The action of decomposers and erosion erased most signs of past terrestrial organisms, and existent fossils usually correspond to individuals that were trapped and died in good preservation settings, such as volcanic ashes or tar pits (Raup, 1992). The best records of fossil vertebrates are for temperate terrestrial mammals (Regan *et al.*, 2001; Barnosky *et al.*, 2011).

The assessment of present and future extinction rates mostly relies on terrestrial vertebrate data for which there is more data available. With the exception of terrestrial mammals, the differences in the composition of past and recent extinction records limit the comparison between past and current extinction rates. Therefore, it is important to improve our knowledge on the conservation status of groups that are well represented in the fossil record but currently less known, such as near-shore marine invertebrates with shells (Barnosky *et al.*, 2011). A caveat would be that selected groups might not be good indicators of other taxa, ascribing a limited utility to comparisons.

A second problem relates with the taxonomic levels used to assess extinction rates and with the concept used to define species (Barnosky *et al.*, 2011). Fossil diversity and extinction rate are usually assessed at the genus level, and species diversity and extinction rate are then extrapolated using species-to-genus ratios, based on proportions of well-known groups. However, modern extinction rates are directly based on species data. Moreover, species in the fossil record are defined using the morphological species concept, whereas modern species are often defined using other criteria, especially the phylogenetic species concept, based on genetic similarity. The type of concept used may affect the number of species in a taxon and influence extinction rate metrics, adding uncertainty to extinction rate comparisons.

A third source of uncertainty when comparing extinction rates is that past extinction rates represent a measure of realized extinction, current extinction rates represent a conservative measure of recent extinction, due to the omission of “possibly extinct” species, and projected extinction rates may represent an overestimated measure of extinction rate, due to the inclusion of species committed to extinction.

Key Messages

Human activities and intervention over ecosystems have been causing the loss of species at rates much higher than the

natural rate of extinction. Earth is experiencing a biodiversity crisis and while a sixth mass extinction is still avoidable, modern rates of extinction are already too high and alarming. Although developed regions, namely Europe, have already lost an important share of their biodiversity during millennia of human occupation and resources exploitation, other regions, namely species-rich tropical regions are now experiencing intense human pressure, which may lead to very high rates of biodiversity loss. The risks of biodiversity loss, from species loss to ecosystem degradation, are real and may jeopardize human well-being by affecting the delivery of critical ecosystem services, including food, clean water, and regulation of natural disasters.

Despite these risks our knowledge of biodiversity and of the complex interactions between drivers of change and between them and natural systems is still very incomplete, and limits our capacity of action to target and develop measures to halt biodiversity loss. There is a need for a better understanding of the impacts of drivers on biodiversity, especially of drivers that are still weakly integrated in projections of future biodiversity change (i.e., land-use change, overexploitation, pollution, and invasive species), but there is also a need for data from regions where biodiversity is now under more severe pressure. The implementation of a global network for biodiversity monitoring (Pereira *et al.*, 2010a, 2010b) that delivers data to fill knowledge gaps and to validate and calibrate current models of biodiversity change may contribute to reduce uncertainty in projections and hence to better assess impacts of drivers on biodiversity and relevant conservation measures.

Glossary

Ammonites Shelled group of invertebrates related to octopus, squid, and nautilus.

Amniota Taxon of vertebrates including mammals and reptiles (including birds).

Archaic ungulates (or condylarths) Extinct group or grade of mammals possibly giving rise to hoofed mammals.

Chondrichthyans Sharks and their relatives.

Ectotherm Animals that produce their heat from external sources such as the Sun.

Endotherm Animals that produce their heat internally through metabolic means.

K/T Abbreviation for Cretaceous/Tertiary, usually in reference to the K/T boundary.

Nonavian dinosaurs Dinosauria excluding birds.

Ornithischians Bird-hipped dinosaurs such as horned and duck-billed dinosaurs.

Palynomorphs Pollen and spores produced by plants.

Saurischians Reptile-hipped dinosaurs such as theropods.

Sixty-five and a half million years ago, a 10 km diameter rock from space slammed into the Earth, almost instantly annihilating over 70% of all species, including all nonavian dinosaurs. Textbooks, the press, and many scientists have accepted some version of this Cretaceous/Tertiary (K/T) mass extinction scenario for over 20 years. Yet, even as the popularity of this single-cause explanation increased, nagging questions continued to be voiced as to the possible biologic effects of such an impact event. This is particularly true with regard to the record of plants and animals living on land and in freshwater habitats. For example, 12 clades representing about 107 species of better-studied vertebrates known from very near the K/T boundary in western North America suffered 51% extinction. Of these 12, however, only five—chondrichthyans, lizards, marsupials, ornithischians, and saurischians (without birds)—account for 75% of the extinctions. The obvious biological question is what did sharks, lizards, opossums, and nonavian dinosaurs have in common that made them collectively more susceptible to extinction, especially from the environmental consequences of a large bolide impact? Other statistically significant patterns emerge as well (**Figure 1**). Chances of survival were much lower if you were a large, terrestrial, amniotic endotherm rather than a small, freshwater, anamniotic ectotherm. None of the myriad of Dante's inferno events (e.g., sharp temperature increase, sharp temperature decrease, tsunamis, hurricanes, global wildfires, and acid rain) alleged or modeled to have occurred in the wake of this impact have been able to explain these curious extinction and survival patterns. In fact, several of these so-called inferno events have been discounted completely (e.g., acid rain, because most aquatic species survive), or are regarded as unlikely (e.g., sharp temperature decrease, because ectotherms do well) when tested against the known K/T fossil record.

Yet Another Dante's Inferno

A recently proposed postimpact environmental scenario may be the first that shows some broad agreement with the

vertebrate fossil record (**Robertson *et al.*, 2004**). This scenario postulates that, following the K/T impact, ejecta reentering the atmosphere created an intense blanket of infrared radiation that covered the planet's entire surface. Such a pulse of intense thermal radiation would kill any unsheltered organisms. The radiation scenario predicts that aquatic organisms would have been sheltered from the searing thermal pulse by a layer of water. This might explain the survival of most aquatic species. Terrestrial forms, however, would have suffered greatly unless they found shelter underground or in some sort of natural cavity. At first blush, this mechanism appears to explain why typically larger dinosaurian species fared more poorly than did some mammals. It may not actually be large size itself that was being selected against. Dinosaurs grew from a small size after hatching from eggs and some may even have been small enough after leaving any parental care to have survived in some sort of cavity. But in such cases, there would have been enough survivors to form a viable postimpact population to ensure species survival. For the smaller mammals, it is given that much larger population sizes would have predominated. Indeed, their numbers in the fossil record indicate this. By virtue of these larger population sizes, coupled with small physical size, more individuals may have been able to shelter in some sort of cavity or underground, and then emerge to reassemble their population.

This is all well and good, but how does the infrared radiation scenario explain the fact that placental mammals fared much better than marsupial mammals in North America, while in South America both groups radiated in the Early Tertiary? Similarly, under this radiation scenario, why would the clearly aquatic sharks disappear completely? In the marine realm, this scenario becomes even more unsatisfactory as it fails to account for the distinction between victims as disparate as nannoplankton, planktonic foraminifera, ammonites, and marine reptiles and survivors as disparate as benthic foraminifera, sponges, corals, lophophorates, and echinoderms. Many of these groups exhibit

Figure 1 Differential patterns of vertebrate species survival at the K/T boundary (Archibald and Fastovsky, 2004). χ^2 tests of comparisons, except possibly the last, are significant (freshwater versus land-dwelling comparison and ectothermic versus endothermic comparison, $P < 0.005$, small versus large comparison, $0.010 < P < 0.025$, nonamniote versus amniote comparison $0.150 < P < 0.100$). Reproduced from Archibald JD and Fastovsky DE (2004) Dinosaur extinction. In: Weishampel DB, Dodson P, and Osmolska H (eds.) *The Dinosauria*, 2nd edn., pp. 672–684. Berkeley: California University Press.

patterns of species-richness turnover that are not consistent with a single-event scenario located at the very end of the Cretaceous. Indeed, even the timing of impact-related event scenarios has recently been rendered much more complicated by the discovery of evidence that the Chicxulub impact may have predated the K/T boundary by as much as 300 ky.

Back on land, there are still other unresolved questions. The radiation scenario predicts that heightened infrared flux would have caused global wildfires. Whether this is a necessary correlate remains to be seen, but others have argued that the physical evidence does not support the occurrence of a global wildfire at the K/T boundary. Thus, although it is a promising mechanism, this latest Dante's inferno scenario requires much further study before postimpact reentry infrared radiation can be accepted as either a partial, or the predominant, mass-extinction killing mechanism.

Multiple Causes

Other events that clearly occurred at the K/T boundary also fit the known pattern of vertebrate extinction in western North America, notably the loss of most epicontinental seas from the middle of the continent shortly before the K/T boundary. This was the greatest such loss in the past 250 My of Earth history. How it may have contributed to the K/T extinctions is not always straightforward, with one obvious exception. Shark species that frequented the rivers of western North America would have followed the regressing seas. Thus, their absence in the earliest Paleocene of this region is no great mystery. Different shark species made a brief reappearance when the seas once again lapped interior North American shores for a short time in the Early to Middle Paleocene. Aquatic species, except the fore-mentioned sharks, generally did well across the K/T boundary as the freshwater systems expanded in the wake of the sea's retreat.

But what of the marsupials? One possibility is that the earliest archaic ungulates (or condylarths) that definitely appear in North America in the earliest Paleocene (but probably were around by the latest Cretaceous) may have out-competed the marsupials in North America. The geographic origin for these archaic ungulates is uncertain. More and more evidence, however, points to Asia. As sea level fell, archaic ungulates presumably crossed the perennially appearing Bering Land Bridge. In South America, instead of replacing the marsupials, local ungulate lineages shifted more and more to herbivory while the marsupials remained omnivores or became more carnivorous.

Latest Cretaceous dinosaurs, which are only known in any numbers from low coastal plains, would have decreased in population size as the marine regression progressed. Such habitat loss is similar to that caused by human disturbance. It is doubtful that this alone would have been sufficient to cause the demise of dinosaurs, but we do know that with this sea level regression, global environmental change caused by increased volcanism from the Deccan Traps, and the terminal Cretaceous impact, the stresses on these creatures would have been great.

Long-term Trends in Dinosaur Diversity

The events discussed thus far occurred over hundreds of thousands of years in the case of the multiple-cause hypotheses (marine regression, habitat fragmentation, volcanism, and impact), or possibly over as short a span as hours–years in the case of an impact. The problem has been that to examine these competing views more thoroughly, we need a longer record stretching back millions, if not tens of millions, of years. Nowhere is this more keenly felt than in the question of what was happening to the dinosaurs during the close of the Cretaceous. The two components of this issue are: (i) What happened during the last 10 or so million years of the Cretaceous? and (ii) What happened during the last million years or less? Although among the rarest of almost any vertebrate species in the Late Cretaceous, dinosaurs have become the poster-children for this extinction. Not surprisingly then, this group has received most of the scientific attention as well. Because its stratigraphic record is far more complete through

this geological interval, once again, most work centers on western North America.

For at least the past 25 years, the general view was that the 75-million-year-old, Late Campanian beds in western North America held the richest known dinosaur fauna and that there was a substantial taxonomic decline by about 66 Ma, just before the terminal Cretaceous extinctions. There were a few who argued that this was the result of more poorly known latest Cretaceous dinosaur faunas, but the vast majority of studies found this to be a true decline in taxonomic diversity in the waning 10 My of the Cretaceous, something on the order of 40%.

A recent study has attempted to resuscitate this issue within the context of examining dinosaur diversity throughout the Mesozoic Era, in which the authors concluded that their data did not support a claim that dinosaur richness was decreasing toward extinction during the last 1 My before the K/T boundary (Fastovsky *et al.*, 2004). Separate from the issue of whether dinosaurs were decreasing toward extinction, the question at hand is how one can conclude dinosaurs were not declining in taxonomic diversity during the last 10 My of the Cretaceous. Even in such studies the results show a decline of genera going from the Late Campanian (about 75 Ma) into the Late Maastrichtian (about 65 Ma). These patterns of decline have been attempted to be explained by rarefaction analysis. Fortunately, a newly published compendium of dinosaur distribution has allowed tabulations of taxa for succeeding intervals of time.

Table 1 is a generic compilation from this new compendium. Comparing taxa at the generic level rather than at the species level can be problematic, but in this case most of the genera are either monotypic or only one species is known from a given fauna. Only genera identified without qualification are included in **Table 1**. Similarly, only localities were used for which unambiguous age ranges were provided. The compilation in **Table 1** is based on standard geological divisions of Early and Late Campanian, and Early and Late Maastrichtian.

Both the Early Campanian and Early Maastrichtian have a quite low diversity, which are almost certainly artifactual. This is supported by the fact that five genera (*Avisaurus*, *Leptoceratops*, *Pachycephalosaurus*, *Pentaceratop*, and *Troodon*) reported from the Late Campanian and Late Maastrichtian are not identified from the intervening Early Maastrichtian. The Late Campanian and Late Maastrichtian of North America are much better sampled intervals, with an obvious decline from 48 to 32 genera—a 33% drop. This is the case even though there are four more localities and 27 more repeated generic samplings for the North American Late Maastrichtian compared with the Late Campanian.

Although the drop in generic richness is clear, one could argue that such broad-brush geographic comparisons are not ecologically meaningful. To examine this concern, one can compare more clearly delineated faunas rather than make comparisons across the board (**Table 2**). For the Late Campanian, the richest dinosaurian fauna is from the Dinosaur Park Formation, Alberta, which includes 31 genera and 38 to 42 species. A recent reassessment of this fauna's age brackets it between about 76.5 and 74.2 Ma within Dinosaur Provincial Park, Alberta, with the actual span of time represented by this

dinosaur fauna being somewhat shorter, by about 2 My. For the Late Maastrichtian, the richest fauna is from the Lance Formation, Wyoming, which contains 20 genera and 21 to 22 species. Although ages are not well known for the Lance Formation, the nearby biostratigraphically comparable Hell Creek Formation in Montana spans about the last 1.7 My of the Cretaceous. Comparing these figures shows that, although the Dinosaur Park and Lance Formations sample a similar magnitude of time, there is a 35% generic decline, and up to a 50% species decline between the Dinosaur Park (Late Campanian) and the Lance (Late Maastrichtian) faunas.

What is of particular ecological interest is that this decline is not especially high among the rarer carnivorous theropods, but rather among the more common hadrosaurid and ceratopsian genera. From six hadrosaurid and six ceratopsian genera in the Dinosaur Park fauna, we see a decline to only one hadrosaurid and four ceratopsian genera in the Lance fauna (**Table 2**). Comparable changes have been reported for the similarly aged Hell Creek Formation, but they are less well known for the Scollard Formation, Alberta. Thus for all the cases known, the percent generic and species declines are still over 30 and near 50, respectively, during the last 10 My of the Cretaceous.

Short-term Trends in Dinosaur Diversity

The question of what happened to vertebrates—and especially to dinosaurs—during the last million years or so of the Cretaceous is a less tractable problem. Unlike the broader question of patterns characteristic of the last 10 My of the Cretaceous, in tracking a much finer scale pattern we are now asking much more of the fossil record. The first attempt at quantification of this question counted the number of dinosaur teeth per metric ton of sediment recovered from screen washing samples collected in eastern Montana. Results showed a gradual decrease of dinosaurs leading up to the K/T boundary. As it turned out, all but the lowest sample were from the earliest Paleocene. Consequently, the dinosaur teeth were largely zombie taxa (i.e., taxa reworked from latest Cretaceous sediments). In 1992, another study examined surface-collected dinosaur material within the lower, middle, and upper third of the Hell Creek Formation, North Dakota. No changes in the dinosaur faunas were found throughout the section. Unfortunately, as this study was conducted at the relatively crude taxonomic level of family, a 40% loss of dinosaur species could have occurred without being detected.

In 2002, the results of a study conducted largely by an amateur paleontologist provided the first well-documented sampling of vertebrates through the entire thickness of the Hell Creek Formation in North and South Dakota. Despite a somewhat coarse-level sampling scheme, this study did not find any obvious changes in taxonomic diversity throughout the formation. These results have been used by some as evidence for abrupt dinosaur extinction. In fact, neither the stratigraphic nor the taxonomic levels of resolution employed in these studies are fine enough to address, let alone answer, this question. For example, this study reported that there are 2233 dinosaurian specimens representing 14 taxa. In the 3 m interval below the K/T boundary, there are only 26

^aNumber following each genus is the number of localities at which a particular genus occurs.^bTaxa occur in L. Campanian and L. Maastrichtian, but not intervening E. Maastrichtian.Source: Reproduced from Weishampel DB, Barrett PM, Coria RA, *et al.* (2004) Dinosaur distribution. In: Weishampel DB, Dodson P, and Osmolska H (eds.) *The Dinosauria*, 2nd edn., pp. 517–606. Berkeley: California University Press.

dinosaurian specimens representing just three taxa. Within the upper 5 m of the Hell Creek only two dinosaurs (*Ricardoestesia* and *Tyrannosaurus*) were identified at the generic level. The next higher occurrences of dinosaur genera occur 8 m or lower within the Hell Creek Formation. What of the other 18 or so

dinosaur genera that are known to have occurred in the Hell Creek Formation? Such a record is obviously much too poor to say anything about whether the local dinosaur extinction was instantaneous or gradual on a scale of tens to hundreds of thousands of years.

Table 2 Generic and species counts of dinosaurs for Dinosaur Park Formation (Late Campanian) and Lance Formation (Late Maastrichtian) of North America (Weishampel *et al.*, 2004)

Out with a Whimper, a Bang, or Both?

If questions of rate and taxonomic magnitude of terrestrial extinctions are to be addressed and possibly answered, a much finer scale of both stratigraphic and taxonomic sampling will be required. One study (Figure 2) that specifically addressed changes within the turtle community in the Hell Creek Formation during the last 1.7 My of the Cretaceous found that for

turtles, as well as for mammals and plants, taxonomic richness was lower in the formation and dropped immediately before the K/T boundary. The maximum diversities in these three groups were correlated with the maximum latest Cretaceous warming and the drop in richness was correlated to a rapid drop in paleotemperature. In a detailed study of only the mammals from this same sequence, the observed change in climate was deemed insufficient to explain the extinction or

Figure 2 Compiled taxonomic richness data for plants, mammals, and turtles in the Hell Creek Formation. Independent of taxonomic level, taxonomic richness is lower in the early portion of the Late Maastrichtian and it drops immediately before the K/T boundary. The greatest taxonomic diversity is associated with maximum warmth, while the latest Maastrichtian drop is correlated with a rapid drop in paleotemperature. Reproduced from Hutchison JH, Holroyd PA, Gregory P, and Wilson GP (2004) The possible role of climate on successive turtle assemblages from the Upper Cretaceous Hell Creek Formation. *J. Vertebrate Paleontol.* 24(Suppl. 3): 73A.

pseudoextinction (disappearance resulting from speciation) of up to 27 species of mammal near or at the K/T boundary. A longer, gradual turnover pattern could be ruled out based on this analysis, but the time resolution of these data was not able to differentiate between stepwise and sudden extinction.

Until recently, the well-sampled megafloral (leaves and fruits rather than pollen) record had indicated as much as a 79% plant extinction at the K/T boundary in the northern western interior of the United States and even higher (84%) farther to the south in the United States. With much tighter stratigraphic control, however, this estimate has recently been downgraded to a minimum of 30% extinction based on palynomorphs that have higher stratigraphic but lower taxonomic resolution, compared with a maximum of 57% extinction based on megaflora that disappear within 5 m or less of the K/T boundary. This flora was interpreted then to have suffered between 30% and 57% extinction at the K/T boundary, while other floral extinctions were spread out

within the 50 m of the upper part of the Hell Creek Formation. Certainly, there is a dynamic floral turnover throughout the Cretaceous part of the section, a sharp shift near the K/T boundary, and virtual stasis during the Paleocene; a pattern interpreted as being commensurate with "sudden ecosystem collapse, presumably caused by the Chicxulub impact." Once again, though, while the fact of the taxic richness decline is clear, the time interval over which this decline occurred, and its correlation to alternative sources of global environmental change, are not.

Conclusions

The newest generation of studies on the K/T and dinosaur extinctions shows that extinction levels for plants and animals, on land and in fresh water, are not as great as once thought. Instead of species extinction levels as high as 80%, newer

studies range from a possible low of 30% to a high of, at the most, 60%. Dinosaurs clearly declined in taxonomic richness during the last 10 My of the Cretaceous, at least in North America where they are best known. This is true whether broader geographic taxonomic counts or specific dinosaurian faunas are compared. But the dinosaur record remains too poor to determine what occurred in the last few tens or hundreds of thousands of years of the Cretaceous. The record is better for other terrestrial groups. Taxonomic richness for both plants, and vertebrates—at least turtles and mammals—tracks the climb to a warm maximum and then a sudden plunge in temperature just before the K/T boundary. These records appear sufficient to eliminate a long-term, gradual pattern of extinction leading up to the K/T boundary, but whether the extinctions were stepwise over hundreds of thousands of years, or sudden over as little as a few years cannot be determined, given the record currently available. Moreover, given the certain knowledge that a number of major environmental changes were operating in this latest Maastichtian interval, singling out of any one cause is more a matter of speculation than fact.

This article is a revision of the previous edition article by Raymond C. Nias and John R. Mooney, pp 1–15, © 2001, Elsevier Inc.

Glossary

Biodiversity hotspots A region that contains at least 1500 species of vascular plants (>0.5% of the world's total) as endemics and has lost at least 70% of its original habitat.

Conservation status A classification of species and ecosystems according to their extinction risk; such as vulnerable, endangered, and critically endangered.

Ecoregion A relatively large area of land or water that contains characteristic, geographically distinct assemblages of natural communities, and species.

Ecosystem composition The species or functional groups of organisms found within a given ecosystem.

Ecosystem function The biological and chemical processes that occur within ecosystems such as primary production and nutrient cycling.

Ecosystem structure The different trophic (feeding) levels within an ecosystem and the interactions between them.

Extinction risk The likelihood of extinction of a species with specific demographic characteristics and distribution under various threatening processes over time.

The article outlines recent progress in the development of systematic approaches to the identification of the world's ecosystems and their conservation status. A synopsis is given of how from the mid-1990s through to the present conservation biologists and practitioners have been devising more explicit classifications systems for ecosystem types that has allowed for the identification and mapping of terrestrial, freshwater, and marine ecosystems from the global to local scale. Summaries are provided of these studies as well as recent progress in developing a new and more systematic approach to the classification of extinction-risk for ecosystems. In addition to overall trends derived from global assessments some examples are provided of globally significant ecosystems considered to be endangered.

Defining Ecosystems and their Conservation Status

In contrast to the situation with threatened species, the definition of an ecosystem as a "unit of conservation concern" has been problematic. Difficulties with the identification of distinct ecosystems and what constitutes the extinction of an ecosystem have hampered attempts to develop objective criteria for categorization of ecosystems and their conservation status. The definition of an ecosystem as "a dynamic complex of plant, animal, and microorganism communities and their nonliving environment interacting as a functional unit" (Convention on Biological Diversity, <http://www.cbd.int/convention/text/>) for example, does not define any specific dimensions or boundaries. At the smallest scale there are ecosystems of invertebrates and microbes that exist within a few liters of water or a few kilograms of soil. In fact each ecosystem is nested within a larger ecosystem up to the scale of the biosphere which can be considered as a single planetary ecosystem. Apart from the question of scale, ecosystems are also dynamic, with many natural changes both in areal extent and composition occurring over time. In aquatic ecosystems, for example, the area covered will fluctuate with changing

water levels, floods, and tides and entire ecosystems such as ephemeral wetlands may come and go in the space of a few months. Terrestrial ecosystems are typically defined by their major vegetation type such as moist broad-leaved (tropical) forest or lowland temperate grasslands, but may also be characterized by unique physical features such as particular geological substrates (e.g., lime-stone-based karst ecosystems). In the marine environment ecosystems may be defined geographically and also by particular attributes of water temperature or chemistry, or by the characteristics of the substrate (e.g., rocky, sandy, or muddy bottoms). Specific plant and animal communities such as seagrass beds, kelp forests, and coral reefs may also form part of the definition of a particular marine ecosystem.

For individual species, the identification of conservation status as measured by the degree of extinction risk has been widely accepted for decades. Species are classified into various categories (such as not at risk, of least concern, vulnerable, endangered, and critically endangered) based on well-established criteria that relate to overall population size and trends (Mace *et al.*, 2008). In relation to species the idea of biological extinction is relatively easy to define but for ecosystems made up of multiple species this is far more difficult. In a pioneering study of North American ecosystems Noss *et al.* (1995) described ecosystem loss as taking two forms: quantitative loss and qualitative loss. Quantitative loss is the decline in areal extent of a discrete ecosystem type (e.g., the conversion of a native prairie grassland into a corn field) while qualitative loss is a change or degradation in the structure, function, or composition of an ecosystem (e.g., the change in species composition of a steppe ecosystem due to overgrazing, or the removal of key predator species in a marine ecosystem through overfishing). Problems arise when the concept of extinction risk is applied to ecosystems and the extent to which the loss of any species from an ecosystem impacts on the overall ecosystem structure and function is still the subject of much uncertainty and research (Duffy, 2003; Thébault *et al.*, 2007). Despite these obvious difficulties there have been

arguments made to codify the conservation status of ecosystems from at least the mid-1990s (e.g., Noss, 1996) to the present (Rodríguez *et al.*, 2007, 2011; Nicholson *et al.*, 2009).

Assessments of Endangered Ecosystems

Some of the first systematic reviews of the conservation status of particular ecosystems were carried out in the early 1990s including tropical rivers in Asia (Dudgeon, 1992) and North American ecosystems (Noss *et al.*, 1995). The ongoing development of systematic approaches for mapping ecosystems at large scales – much of which is based on the concept of geographically and biologically distinct areas or “ecoregions” (Dinerstein *et al.*, 1995) – has led to the identification and mapping of global terrestrial (Olson *et al.*, 2001), freshwater (Abell *et al.*, 2008), and marine (Spalding *et al.*, 2007) ecoregions. Although “ecoregions” and “ecosystems” may not necessarily be the same thing, systematic methods to describe spatial patterns of biodiversity distribution have greatly facilitated global overviews as well as continental-scale assessments of terrestrial and freshwater biodiversity (e.g., Burgess *et al.*, 2004; Thieme *et al.*, 2005, among others). Significant milestones in the application of systematic approaches to ecosystem conservation include the identification of threatened biodiversity hotspots (Myers *et al.*, 2000) priority ecoregions (Olson and Dinerstein, 1998), globally significant wilderness areas (Mittermeier *et al.*, 2003), and key biodiversity areas (Eken *et al.*, 2004) and the synthesis of these approaches (Brooks *et al.*, 2006). Finer-scale approaches can also assist in identifying alternative strategies for prioritizing conservation efforts within a particular ecosystem; and this has been well demonstrated in places as diverse as the Cape Floristic Region of South Africa (Cowling and Pressey, 2003), the Atlantic forests of Brazil (Paese *et al.*, 2010) and the Great Barrier Reef of Australia (Fernandes *et al.*, 2005). There are also some long-established monitoring programs that track trends in conservation status of ecosystems over time (e.g., coral reefs; Wilkinson, 2008). Recently the International Union for Conservation of Nature (IUCN) has begun work on a classification scheme for threatened terrestrial ecosystems that intends to build on the successful application of the Red List of Threatened Species and protocols in use by some government conservation agencies (Rodríguez *et al.*, 2011). This system proposes the use of a naming system analogous to the present IUCN species-specific system (Least Concern, Vulnerable, Endangered and Critically Endangered) using four criteria: (A) reduction of land cover and continuing threat, (B) rapid rate of land cover change, (C) increased fragmentation, and (D) highly restricted geographical distribution. However a number of challenges remain to be solved and it remains unclear to what extent important changes in species composition (such as the loss of a key predator species for example) can be incorporated into this approach.

The Millennium Ecosystem Assessment (MA)

The Millennium Ecosystem Assessment (MA) (2005) was called for by the United Nations Secretary-General in 2000

and was initiated in 2001 through the United Nations Environment Programme (UNEP). The purpose of the MA was to “assess the consequences of ecosystem change for human well-being and to establish the scientific basis for actions needed to enhance the conservation and sustainable use of ecosystems and their contributions to human well-being.” The report includes global overviews of marine, coastal, inland water, forest, dryland, island, mountain, and polar ecosystems as well as 18 subglobal assessments. The conclusions of the MA are stark in their portrayal of ecosystem loss; stating that “virtually all of Earth’s ecosystems have now been dramatically transformed through human actions.” Over half of the 14 biomes that the MA assessed have experienced a 20–50% conversion to human use, with temperate and Mediterranean forests and temperate grasslands being the most affected. Marine ecosystems have also been badly affected with 20% of coral reefs and 35% of mangrove ecosystems being lost in the past few decades.

General Trends in Conservation Status of Major Ecosystem Types

Terrestrial Ecosystems

Forest ecosystems currently occupy approximately 31% of the Earth’s land surface and are estimated to contain more than half of all terrestrial animal and plant species, the great majority of them in the tropics. In most of the world the major threat to forest ecosystems is conversion to agricultural land. According to the third United Nations Global Biodiversity Outlook (<http://gbo3.cbd.int/home.aspx>) nearly 130,000 km² of forest were converted to other uses or lost through natural causes each year from 2000 to 2010, compared to nearly 160,000 km² per year in the 1990s. Many tropical moist forest ecosystems are considered to be endangered, particularly in western Africa, the lowland forests of Southeast Asia, the Atlantic coast of Brazil, and forests on islands such as Madagascar, Indonesia, and the Philippines. Although rapid development of these regions for agriculture and large-scale commercial logging has been primarily responsible for this extensive forest loss, large-scale fire now poses a major problem in some of the previously contiguous forests of Indonesia and Malaysia, especially during periods of prolonged drought. Similar problems are faced the seasonally dry forests, especially the monsoonal forests and conifer forests such as those found in Central America and Madagascar. Owing to their restricted distribution the monsoonal forests and conifer forests in the tropical and subtropical regions of the world are among the most endangered of forest ecosystems. The biologically rich dry forests of Madagascar for example are now much reduced but still some of the richest forest ecosystems in the world in terms of their natural diversity. Most of the forest has been cleared for slash-and-burn agriculture, pasture, firewood, or construction materials and secondary grasslands now cover most of the region. The remaining fragments of forest are steadily being degraded and lost as a result of uncontrolled burning of surrounding savannas. Most temperate forest ecosystems of the world have also been modified significantly to increase their commercial timber value at the

Table 1 Examples of some ecosystems and ecoregions commonly referred to as endangered

<i>Region</i>	<i>Terrestrial ecosystems</i>		<i>Freshwater ecosystems</i>		<i>Marine and coastal ecosystems</i>	
Africa	Tropical moist forests	Madagascar forests, thicket, and scrublands	Lakes	Great Lakes (Kivu, Edward, George, Victoria)	Oceans and seas	Canary Current (Eastern Atlantic)

expense of natural complexity and structure and they are more likely to contain uniform, relatively even-aged stands, with little dead timber, and with a significantly reduced complement of animal species. The deliberate introduction of non-native timber species has also altered the composition of temperate forest ecosystems across many parts of the world.

Despite their often uniform appearance, many woodland, heath, and grassland ecosystems are complex and varied, with many regional variations and subtle differences resulting from soil type and climate. They are usually present where soil nutrients, water availability, or climate are not conducive to the growth of forests. Temperate and semiarid scrubs, heaths, and grasslands in particular are well suited to grazing by domestic animals and for conversion to cultivation, especially cereal crops, and as a consequence are among the most modified of the world's major ecosystems. The loss and degradation of semiarid ecosystems is also a key driver for the process of desertification in many parts of the world.

Freshwater Ecosystems

Freshwater ecosystems including rivers and their floodplains, lakes, and wetlands have undergone more dramatic changes than any other type of ecosystem due to a combination of human activities including drainage for agriculture, abstraction of water for irrigation, industrial and household use, the input of nutrients and other pollutants, introduction of alien species, and the damming of rivers. Even if the physical structure of wetlands remains intact, they are often vulnerable to the effects of chemical pollution. Such pollution can significantly modify the ecosystem as key organisms are lost as a result. The use of lake and river water for industrial purposes often affects water quantity (when abstracting water) and water quality (when reintroducing it as wastewater, sometimes polluted, or of higher temperature). Many industries, such as pulp and paper production and mining, wash large quantities of particulate matter into lakes and rivers. Pollution and sedimentation threaten many inland waters and other wetlands. In some cases, the source of this pollution may be distant, with contaminants being transported through the air in the form of industrial emissions. The most significant impact on global freshwater ecosystems however is the removal of water for human use, particularly for irrigation.

Marine and Coastal Ecosystems

Coastal marine ecosystems are among the most productive ecosystems on earth but are also highly threatened by a range of human activities and in particular, pollution from land and ocean-based sources, coastal development, and overfishing. These impacts are being compounded by sea-level rise creating a "coastal squeeze." Coastal ecosystems and near-shore marine areas are among the most threatened of all ecosystem types with some 35% of mangrove ecosystems having been lost or converted, 20% of coral reefs having been destroyed, and up to 20% of coastal wetlands lost in some places of the world on an annual basis (MA, 2005). Recent assessments have shown a high proportion of mangrove and seagrass species – which are the basis of these ecosystem types, are at risk of extinction

globally (Hughes *et al.*, 2009; Polidoro *et al.*, 2010). The loss of these coastal ecosystems also represents a significant loss of natural resources of great importance to many human societies and economies and their importance in storing carbon dioxide is also gaining increased attention (MA, 2005).

The world's oceans contain some of the least explored areas of the world, and only a tiny percentage of the deep seabed has been subject to biological investigation. Nevertheless, studies have revealed a wealth of diverse ecosystem types in the deep sea and some such as seamount ecosystems and cold water coral reef ecosystems are threatened by high-impact fishing methods, such as bottom trawling. Like other ecosystems, marine ecosystems also show the effects of changes in species abundance caused by direct human consumption. The impact of overfishing on marine ecosystems has been the subject of considerable debate in the past 10 years (e.g., Coll *et al.*, 2008). The full impacts of global warming on marine ecosystems are only just beginning to be understood although the predicted impacts may well be catastrophic in many cases (Hoegh-Guldberg and Bruno, 2010).

Although coral reefs occupy a small fraction (<0.2%) of the total area of the world's oceans, they are among the most biologically diverse of all ecosystems. It is estimated that about 20% of the world's coral reefs have been destroyed and an additional 20% is badly degraded or under imminent risk of collapse (MA, 2005). The destruction of coral reefs is caused by many human activities, ranging from coastal development and destructive fishing practices to over-exploitation of resources, marine pollution, and runoff from agricultural activities and deforestation. A number of reefs of particular biological interest are also under the most serious threat, including almost all the reefs of the Philippines and coral communities in coastal Indonesia, Tanzania, the Comoros, and the Lesser Antilles in the Caribbean. Of all the world's ecosystems, coral reefs are among the most vulnerable to the effects of climate change. Coral bleaching events due to high water temperatures events often lead to mass mortality although some recovery may occur given sufficient time between bleaching episodes (Wilkinson, 2008) (Table 1).

Conclusions

Ecosystems are dynamic and range in scale from the biosphere to the microscopic. As a result the exact delineation of an ecosystem and its description as being "endangered" has been a largely subjective matter for many years. There has been progress in the past decade in the identification and description of the world's ecosystems and perhaps the most important advance has been the identification and global mapping of terrestrial, freshwater, and marine ecoregions. Recent work on the development of a systematic set of protocols for defining the conservation status of ecosystems may provide the basis for even more rigorous assessments of the true state of biodiversity to be determined at the global, continental, and regional scale. Overall the conservation trends for ecosystems and biological diversity in general, are extremely negative (Butchart *et al.*, 2010).

Glossary

Aquifer A geological formation that contains and allows movement of ground water.

Endangered species A species that is at substantial risk of extinction as a result of human activities.

Endemic species A species that occurs only over a limited geographical range.

Eutrophication The process of increasing the productivity of an ecosystem by enriching it with nutrients.

Ground water Water that occurs in saturated soils and geological formations beneath the Earth's surface.

Nonnative species A species that has been moved and established outside of its native range as a result of human activities; also called alien species, exotic species, introduced species, nonindigenous species.

The Earth's fresh waters contain an impressive diversity of invertebrate life. More than 100,000 species of have already been described, and tens of thousands of species remain to be discovered and described by scientists. This diversity is not spread evenly over the surface of the globe, but concentrated in local "hot spots," usually ancient lakes, streams, or ground waters. These "hot spots" often contain dozens to hundreds of species of freshwater invertebrates that are found nowhere else in the world. Because fresh waters are such an important resource for people, and have been used intensively for water supply, power, irrigation, fisheries, navigation, waste disposal, and as sites for cities, environmental conditions in many of the world's fresh waters have been altered greatly from their original states. Especially where "hot spots" of diversity coincide with areas of intensive human development, many freshwater invertebrates have disappeared from their native habitats. Some invertebrate species already have become extinct, and thousands more are in danger of disappearing from the Earth. Careful management of fresh waters, especially in "hot spots" of high biological diversity, is needed to prevent catastrophic extinctions of freshwater invertebrates in the next century.

Introduction

Freshwater Invertebrates of the World

Over 100,000 species of freshwater invertebrates have been described, representing about 750 families and 15 phyla (Balian *et al.*, 2008). The world's freshwater invertebrate fauna is actually much larger than this; probably 10,000–100,000 species await discovery, and new genera and families are discovered regularly. We are particularly ignorant about what lives in ground waters, what lives outside of Europe and parts of North America, and small, soft-bodied invertebrates. The most widespread and species-rich groups of freshwater invertebrates are the insects, crustaceans, mollusks, mites, nematodes, and rotifers, but many other groups are common as well. Invertebrates live in nearly all kinds of freshwater

habitats; lakes, rivers, brooks, ephemeral ponds, wetlands, caves, alluvial ground waters, and even hot springs each contain a rich and characteristic invertebrate community. Among important freshwater habitats, perhaps only the deepest ground waters usually lack invertebrates. A typical lake or stream contains a few hundred species of invertebrates representing several dozen families and eight to 12 phyla. By comparison with the better-known vertebrates, freshwater invertebrates possess a wide range of biological traits. Life spans range from days to more than a century. Many invertebrates reproduce sexually, while others reproduce asexually by budding or parthenogenesis, or change their sexuality or mode of reproduction depending on environmental conditions. Some invertebrates produce eggs or other reproductive bodies that remain viable for years to centuries. Freshwater invertebrates include herbivores, bacteriovores, fungivores, predators, and parasites, and exhibit a wide range of specialized morphologies and behaviors to aid in food-gathering. Some even use symbiotic algae to photosynthesize!

Table 1 NatureServe's system for ranking global conservation status of species

GX	Presumed extinct: not located despite intensive searches and virtually no likelihood of rediscovery
GH	Possibly extinct: known only from historical occurrences but still some hope of rediscovery
G1	Critically imperiled: at very high risk of extinction due to extreme rarity (often five or fewer populations) very steep declines, or other factors
G2	Imperiled: at high risk of extinction or elimination due to very restricted range, very few populations, steep declines, or other factors
G3	Vulnerable: at moderate risk of extinction due to a restricted range, relatively few populations, recent and widespread declines, or other factors
G4	Apparently secure: uncommon but not rare; some cause for long-term concern due to declines or other factors
G5	Secure: common; widespread and abundant

What is “Endangered”?

Various terms such as “endangered,” “threatened,” “imperiled,” and “at risk,” have been used to describe species that are in danger of extinction through human activities. Conservation organizations and governments typically have tried to develop a graded series of carefully defined terms, running from species only remotely threatened with extinction to those on the verge of extinction. **Table 1** shows an example of such a system. Here, “endangered” is used loosely to mean a species or population that is at substantial risk of becoming extinct over the next few decades as a result of human activities.

Figure 1 Diagram illustrating general causes of species endangerment. The three solid lines represent different species, and the dashed line shows the probability of long-term species survival below which we regard a species as endangered. The heavy arrow shows the point at which human impacts began. Species 1 and 2 are now endangered, but for different reasons. Species 1 became endangered because it was vulnerable to extinction before human impacts, and was somewhat sensitive to human activities. Species 2 and 3 were not very vulnerable to extinction before human impacts. Species 2 was either highly sensitive to human activities or lived in an area where human activities were intensive, while species 3 was either not very sensitive to human activities or lived in an area where human activities were weak.

Causes of Endangerment

The specific causes of endangerment of freshwater invertebrates are highly varied from case to case. It would be impractical (and probably not very illuminating) to discuss all the known cases of endangerment of freshwater invertebrates. Further, because information about the world’s freshwater invertebrates is still so incomplete, a catalog of known cases of endangerment would be so biased as to be misleading. Instead, the problem of endangerment is discussed here in a more general way, and selected case studies are used to illustrate major points.

In a general way, endangerment is a product of three factors: the pre-existing vulnerability of a species, the pressure of human activities, and the sensitivity of the species to specific human activities (**Figure 1**). Thus, a species may become endangered if it already was vulnerable to extinction before human involvement, if human activities heavily affect most of the regions or habitats that it occupies, or if it is especially sensitive to a particular human activity. Conversely, a species is likely to avoid endangerment only if it evades all three of these conditions. Each of these factors is discussed below in more detail.

Vulnerability of Freshwater Invertebrates

Small Ranges

Many species of freshwater invertebrates had small ranges even before human intervention. Species with small ranges are called narrowly endemic species. For example, half of the 281 North American pearly mussel species were found only in one to three states, even before human intervention. Such species may have had elevated probabilities of extinction through natural catastrophes, and certainly are especially vulnerable to human activities (**Figure 2**). Small natural ranges often arise through a small number of understandable processes. Because these processes are focused in certain regions and on species with characteristic biological traits, narrowly endemic species

Figure 2 Current conservation status of North American pearly mussels (*Unionoida*) as a function of their native range sizes. Narrowly endemic species were found in one to three states and provinces, moderately endemic species in four to six states and provinces, and widespread species in more than six states and provinces.

often are clustered together into small regions and concentrated in certain taxonomic or ecological groups.

Causes of Small Ranges

A primary cause of small ranges in freshwater invertebrates is the limited dispersal abilities of these animals. All freshwater habitats are islands in a sea of terrestrial habitats, and are more or less isolated from other similar habitats. Although streams are connected together into drainage networks, the streams of one drainage network are isolated from those in other drainage networks. The dispersal abilities of freshwater invertebrates, and thus the perceived isolation of freshwater habitats, vary widely. For animals like dragonflies, whose long-lived aerial adults are strong fliers, or ectoproct bryozoans, whose tough resting stages ("statoblasts") are readily dispersed by migratory waterfowl, the separation of fresh waters probably does not present an important barrier to dispersal or gene flow. For other animals, such as fragile groundwater crustaceans that are poor swimmers, avoid the light, and lack tough dispersal stages, adjacent streams or aquifers may be nearly as remote as distant continents, and even small barriers may prevent migration and gene flow. For instance, the present-day distribution of microparasellid isopods nearly follows the pattern of marine beaches from over 20 million years ago (Figure 3), where these species presumably arose and from which they subsequently apparently have been unable to disperse.

The isolation of freshwater habitats may produce small ranges in two ways. First, endemic species with small ranges may evolve in place following infrequent crossing of dispersal barriers, resulting in a group of more or less closely related species whose ranges are separated by barriers to dispersal.

Second, a formerly widespread species may be eliminated from most of its former range, for instance by a changing climate or the arrival of a competitor, stranded in small refuges, and be unable subsequently to disperse out of the refuges. This second mechanism may become especially important for the freshwater biota if humans cause large changes in regional or global climate, especially because habitat alterations and pollution have eliminated many of the natural dispersal corridors between freshwater habitats.

Finally, a species may have a small range because it requires an unusual habitat, which is itself rare. For example, the thermosbaenacean crustacean *Thermosbaena mirabilis* was described from ancient Roman warm baths and is known from only a few thermal springs in Tunisia. Its small range presumably owes to its unusual habitat requirements as well as its limited dispersal abilities.

"Hot Spots" of High Endemism

Because the processes of speciation, extinction, and dispersal do not occur uniformly over the earth, species richness and endemism vary greatly across the world's fresh waters. Some bodies of water contain more than 1000 invertebrate species, many of them unique to that single body of water. At the other extreme, some bodies of water support fewer than 100 invertebrate species, all of them widely distributed. We might expect sites of high richness and endemism to be habitats of great age, habitats where dispersal is limited, either by geographic isolation or by characteristics of the habitat, or habitats that harbor animal groups that are prone to speciate. Thus, many ancient lakes (Baikal in Siberia, Tanganyika, and Malawi in Africa) and river systems (the Tennessee in the United States, the Mekong in southeast Asia) that have not been

Figure 3 Distribution of freshwater microparasellid isopods and Oligocene shorelines (24–37 million years ago). Stippled areas were land during the Oligocene and closed circles show places where freshwater microparasellids have been found.

recently disturbed by glaciation, marine submergence, or desiccation support unique assemblages of invertebrates (Boxes 1 and 2). Many aquifers seem to contain a high proportion of endemic species, probably because both the characteristics of aquifers (slow water flow, tortuous passageways within aquifers, and barriers between aquifers) and the characteristics of their inhabitants (e.g., fragile bodies, strong thigmotaxis) discourage long-range dispersal. Conversely, glacial lakes and temporary ponds rarely support locally endemic species. Although we know many hot spots of freshwater invertebrate diversity, it probably is not yet possible to produce a reliable global map that shows all major hot spots, as has been recently done for freshwater fishes (Abell *et al.*, 2008).

Species with High Endemism

Groups of animals vary in their tendency to form new species with small ranges. As already suggested, narrow dispersal probably allows the development of local species, while broad dispersal probably provides so much gene flow across populations that speciation is unlikely. Other traits that have been suggested to encourage local speciation include a requirement for outcrossing (as opposed to selfing hermaphroditism or parthenogenesis), production of large young, live-bearing (as opposed to egg-laying), and narrow habitat requirements. The importance of each of these (and other) factors is unclear, but it is clear that groups of freshwater invertebrates do differ widely in their degree of endemism. Figure 4 shows two examples. Dragonflies, most of which are strong fliers and easily cross drainage divides, are much less likely to have small

ranges than pearly mussels, which do not readily cross drainage divides. Even the same group of animals may have dramatically different degrees of endemism, depending on the habitat occupied. Thus, groundwater cyclopoid copepods have very much smaller ranges than their relatives in surface waters. This difference presumably arises because groundwater animals have distinctive behaviors and especially because dispersal between aquifers is more difficult than dispersal between lakes or streams.

Traits of Narrowly Endemic Species

Narrowly endemic species may possess traits (other than small range size) that influence their vulnerability to endangerment. For example, the limited dispersal abilities and specialized habitat requirements of many narrowly endemic species may make them particularly sensitive to and slow to recover from catastrophes, whether natural or human-caused. Further, some environments that contain endemic species may encourage the development of traits that influence species vulnerability. Thus, in the food-poor groundwater environment, many animals have sparse populations, delayed maturity, and low reproductive rates, all of which probably add to their sensitivity to human impacts.

Sparse Populations

Species may be vulnerable to endangerment because their populations are sparse. Because population densities of freshwater invertebrates are much less well known than their geographic ranges, relatively little is known about the

Box 1 Lake Baikal, Russia

Lake Baikal, part of a rift system in southeastern Siberia, is the oldest (>25 million years old) and deepest (>1600 m deep) lake in the world, and covers 31,500 km². It is the only great rift lake that is oxygenated to its bottom, allowing colonization of the entire lake by a wide range of invertebrates. So far, more than 1400 species of invertebrates have been found in the lake, about 60% of which live nowhere else in the world (Kozhov, 1963; Kozhova and Izmet'eva, 1998). Many genera and several families of invertebrates (including the Lubomirskiidae [Porifera], Baicalarciidae [Turbellaria], Baicaliidae [Gastropoda], Benedictiidae [Gastropoda]) are endemic to Baikal. Probably the most remarkable group of endemic species in Baikal is the huge flock (seven families, 72 genera, and >350 species) of endemic gammaroid amphipod crustaceans (Figure 7). These amphipods, which constitute about half of all known gammaroid species in the world, have diversified into a wide range of morphologies and behaviors, and occupy a wide range of ecological niches, including planktonic and benthic herbivores, detritivores, and predators, and semiparasites on sponges. New species of invertebrates are found regularly in Baikal, so it is clear that the true diversity in the lake is even higher than these figures imply. A distinctive feature of the Baikal fauna is that, while nearshore areas contain a mixture of endemic and widespread species, the open water and abyssal sediments are inhabited chiefly by Baikalian endemics.

In many ancient lakes (e.g., Victoria in Africa, Biwa in Japan, Lanao in the Philippines), pollution, habitat destruction, overfishing, and introductions of nonnative species have extinguished many endemic species (Martens *et al.*, 1994; Rossiter and Kawanabe, 2000). Baikal has been protected by its remoteness and vast size, and its fauna has so far been relatively unaffected by human activities. Nevertheless, industrial and domestic waste and siltation arising from deforestation of the catchment have polluted nearshore areas. Although lakewide water quality seems not to have suffered yet, pollution is a concern in Baikal because the long residence time of water in the lake means that contaminants entering Baikal may remain in the lake for a very long time. In addition, nonnative species (e.g., including several fish and the aquatic plant *Elodea canadensis*) have the potential to affect the nearshore fauna. Baikal is a remarkable example of an ancient lake with a richly endemic invertebrate fauna which may yet be preserved through careful management.

The lower panel shows the number of biogeographic regions occupied by groundwater and surface-water cyclopoid copepods in Europe.

occurrence of sparse populations of freshwater invertebrates. Likewise, relatively little is known about the causes of population sparseness, or about how population density per se affects the probability of species extinction. Generally, large-bodied animals have lower population densities than small-bodied animals, and predators have lower population densities than their prey, although many exceptions exist to these generalizations. Further, population densities often are lower near the edge of a species range than in its center, and may be lower in unproductive habitats than in more productive habitats. Thus, we might expect to find sparse populations especially in large-bodied invertebrates and in unproductive habitats like deep lakes and ground waters.

Pressure of Human Activities

Human activities endanger freshwater invertebrates in many different ways (Dudgeon *et al.*, 2006). Here, five broad classes of important activities that are especially important in altering fresh waters and endangering their inhabitants are simply recognized.

Figure 5 Status of the 91 species of freshwater mussel species that formerly occurred in the Tennessee River (USA), which now consists largely of a series of reservoirs. Reproduced from Benz GW and Collins DE (eds.) (1997) *Aquatic Fauna in Peril: The Southeastern Perspective*. Decatur, GA: Southeast Aquatic Research Institute, Lenz Design and Communications. Special Publication 1.

Habitat Destruction and Degradation

Humans have massively altered the physical characteristics of many fresh waters, usually without considering consequent effects on the biota. These physical alterations probably are the largest cause of endangerment of freshwater invertebrates. Dams have been especially damaging (e.g., Figure 5). Above dams, running-water habitats are converted into artificial pools usually unsuited to the native invertebrate species. Below the dam, the water temperature and flows of water and sediment often are so altered that downstream reaches support a highly artificial biota as well. Finally, the dam itself is a barrier that blocks normal migrations and movements of the riverine biota. Thus, even a single dam may endanger the riverine biota for hundreds of kilometers, and many river systems are now dismembered by dozens or hundreds of dams. Over the long term, fragmentation of river systems by dams and other barriers may prevent local populations from recovering from local catastrophes or normal population fluctuations, and thereby increase extinction rates.

In many rivers and streams, floodplains and other shallow-water marginal habitats have been destroyed by dredging, channelization, or filling, or separated from the main channel by dikes and levees. Further, humans often simplify shoreline habitats in both lakes and streams by straightening or filling shorelines and removing "debris" along and in the water. Because marginal habitats often are important for the feeding and spawning of the freshwater biota, the loss or isolation of these habitats may have grave consequences for the native biota. When water is removed from a river for irrigation or held up in a reservoir for hydroelectric generation or flood control, downstream reaches may dry up or lose critically important floods. Several of the world's major rivers (e.g., the Colorado, the Nile) no longer flow to the sea during dry periods. Likewise, the drawdown of many of the world's aquifers from overuse of ground water presumably has major effects on the groundwater biota, although these effects have scarcely even been studied. Finally, mining of underwater

deposits (for gravel or gold, for instance) may have devastating effects both at the site of mining, as well as far downstream through sediment transport and far upstream through head-cutting of the stream bed.

Pollution

Water pollution is another widespread activity with severe effects of freshwater invertebrates. Rivers and lakes often have been used for waste disposal. These wastes include sewage and other organic matter, the decomposition of which may reduce concentrations of dissolved oxygen to levels too low to support most species of invertebrates. Other wastes include substances (e.g., mercury used in gold mining, acid precipitation from power plants and automobiles) that are directly toxic to freshwater invertebrates. Particularly in industrialized regions, long reaches of streams and rivers have been nearly sterilized of invertebrates as a result of severe, chronic pollution (e.g., Figure 6). In addition to pollution caused by deliberate waste disposal, pollution may arise from a wide range of human activities in the watershed. Thus, conversion of forests or native grasslands to agricultural fields or cities typically greatly increases loadings of sediments, nutrients, and toxins that are washed in from the altered watershed. These “nonpoint-source” pollutants are more difficult to track down and control than point loadings of pollutants from factories, yet may have equally serious effects on freshwater ecosystems. While pollution has come under partial control in many developed parts of the world, residual pollution from past releases and inadvertent spills still damage the freshwater biota. Spectacular recent examples include a large spill of pesticides into the River Rhine following a fire at the Sandoz chemical plant, which killed fish and invertebrates for hundreds of kilometers, and the overturning of a truck that spilled a rubber accelerant into the Clinch River, Virginia, which killed most aquatic animals in a 10-km reach, including hundreds of endangered mussels, the largest “take” of endangered species in the United States since the Endangered Species Act was passed in 1973. Of course, in many less developed parts of the world, water pollution is still poorly controlled.

Figure 6 Destruction of the freshwater mussel fauna in the Clinton River, Michigan (USA), in the mid-twentieth century by pollution from the city of Pontiac.

Direct Harvest

Some freshwater invertebrates are harvested for human use, which may contribute to their endangerment. Freshwater mussels have been fished for their shells, pearls, and meat since prehistoric times. Especially in the nineteenth and twentieth centuries, harvest rates became so high that many populations were locally depleted in Europe and North America. For example, over 13 million kg of shells from living unionids were taken from streams and rivers in the state of Illinois in a single year. Harvests of Australian crayfish from the wild reached hundreds of tons year⁻¹, and have contributed to the endangerment of some species. Other invertebrates are collected for bait or the pet trade, which may contribute to local depletion of populations. Invertebrates sometimes are protected by harvest regulations (e.g., closed seasons, size regulations, bag limits), but such regulations may be inadequately conceived and poorly enforced. Fortunately, for economic reasons, harvests usually (but not always) concentrate on common species rather than rare ones.

Nonnative Species

Humans often move species outside of their native ranges. Such introductions may be deliberate, such as the stocking of trout throughout much of the temperate world, or inadvertent, such as the widespread movement of species in ships' ballast water. Whatever the cause, these nonnative species often have strong ecological impacts, and sometimes are responsible for the endangerment of freshwater invertebrates. A spectacular example is the loss of native unionid mussel populations throughout much of northeastern North America as a result of competition with the introduced zebra mussel (*Dreissena polymorpha*). It is projected that the zebra mussel will be the final blow that will drive several species of unionids into global extinction. Nonnative species may also serve as important predators of freshwater invertebrates, as in the case of the brown trout (*Salmo trutta*), which when introduced to Tasmania apparently preyed on and reduced the range of the unusual and endemic anaspidacean crustacean *Anaspides tasmaniae*. Because the effects of nonnative species tend to be cumulative and difficult to reverse, this is a difficult and growing problem in invertebrate conservation.

Global Climate Change

Humans have changed the chemistry of the earth's atmosphere so much that large changes in global climate are expected in the twenty-first century. At this point, it is difficult to make precise predictions about how these changes will affect specific bodies of fresh water. In many bodies of water the changes may be varied and large, involving such diverse characteristics as temperature, hydrology, water level, rising sea level, stratification, the nature and severity of disturbances, increases in damaging ultraviolet light, water chemistry, riparian vegetation, and food quality. Further, in regions where fresh water becomes scarcer while human demands for water continue to grow, human destruction and degradation of freshwater habitats probably will become more severe. Even though we cannot yet specify the details of global climate

change, it is almost certain that this change will endanger or extinguish many freshwater invertebrate species. A rapid, large change in climate will make habitats unsuitable for some of their native species. To survive, such a species will have to disperse to a body of water with suitable ecological conditions. As we have seen, though, the dispersal rates of many freshwater invertebrates are slow, almost surely too slow to keep up with the pace of climate change that current models

predict. Further, human modifications to waterways (e.g., impoundments) probably have made long-distance dispersal more difficult.

Number and Distribution of Endangered Freshwater Invertebrates

How many of the world's freshwater invertebrates are endangered, and where do they live? The most comprehensive list of endangered animals available is the IUCN red list, which includes 1665 species of freshwater invertebrates (Table 2). Although an enormous amount of work by experts went into compiling the IUCN list, it is clearly incomplete. The list is dominated by large, conspicuous, and attractive animals (mollusks, decapods, dragonflies, and damselflies). There is no reason to believe that smaller and less attractive animals are less endangered, but there is simply insufficient information on the status and trends of their populations to identify many endangered species. Likewise, most IUCN-listed species are from North and Central America, Australia, or Europe, which probably reflects the geographical distribution of conservation biologists as much as the actual distribution of endangered freshwater invertebrates.

Another way to assess global endangerment of freshwater invertebrates is to examine where damaging human activities coincide with areas of high endemism (Table 3). Areas where freshwater invertebrates are especially likely to be endangered include river systems throughout much of the unglaciated world, ground waters and springs in arid and semiarid regions, and many industrialized areas.

Except in or near areas covered by Pleistocene ice, recently emerged from the sea, or desiccated, river systems often support species that are endemic to that drainage basin. Most river systems have been very highly modified through impoundment and other physical modifications, water withdrawals, and pollution. Thus, we could project that most old river systems probably contain endemic invertebrates, and that many of these invertebrates probably are endangered as a result of human activities (Box 2). Only species that are good dispersers and thus live in many drainage basins or are habitat

Table 2 Number of species of freshwater invertebrates included on the 2010 IUCN red list of extinct, endangered, or vulnerable animals, by taxonomic group and continent

Turbellaria (flatworms)	1
Gastropoda (snails, limpets)	634
Bivalvia (clams, mussels)	143
Amphipoda (scuds)	71
Synbranchia (anaspideans, bathynellaceans)	4
Cladocera (water fleas)	8
Anostraca (fairy shrimps)	25
Conchostraca (clam shrimps)	4
Notostraca (tadpole shrimps)	1
Copepoda (copepods)	74
Decapoda (crayfish, crabs, prawns)	359
Isopoda (sow bugs)	35
Ostracoda (seed shrimps)	13
Other crustacea	5
Ephemeroptera (mayflies)	3
Plecoptera (stoneflies)	3
Odonata (dragonflies, damselflies)	255
Coleoptera (beetles)	23
Trichoptera (caddisflies)	4
North and Central America	542
South America	61
Africa	296
Europe	299
Asia	268
Australia	196

Total	1665

Table 3 Expected global patterns of endangerment of freshwater invertebrates as a function of human activities

Activity	Geographic distribution	Groups of animals affected
Impoundment	Global, especially North America, China, India, arid regions	Many, especially migratory species or those that depend on flooding or turbid water
Physical alterations (diking, channelization, shoreline modification)	Global, especially highly developed regions	Many, especially those that depend on marginal habitats (shallows, floodplains)
Water withdrawal	Global in arid and semiarid regions	Many, perhaps especially species of ground waters and springs
Toxic pollution	Global, especially industrialized regions	Most species
Eutrophication	Global, especially densely populated or farmed regions	Species of lake profundal sediments or plant beds
Harvest	Locally important throughout the world	Bivalves, decapods, sometimes others
Nonnative species	Global in surface waters, perhaps rare in ground waters	Many
Climate changes	Global, especially in high latitudes	Many, perhaps especially species that disperse poorly

Figure 7 Endemic gammarid amphipods from Lake Baikal, showing some of the wide diversity of body forms. Body lengths are 1.5–6 mm. Reproduced from Salemaa H and Kamaltynov R (1994) The chromosome number of endemic Amphipoda and Isopoda – an evolutionary paradox in the ancient lakes Ohrid and Baikal. *Archiv für Hydrobiologie, Ergebnisse Limnologie* 44: 247–256.

generalists and thus occur in nonriverine environments are likely to escape endangerment. Human impacts on rivers are almost global, and even river systems that have not yet been heavily impounded and modified (e.g., some basins in southeast Asia and central Africa) are facing impoundment and other large modifications in the coming decades.

A second area where we might expect to find many endangered invertebrates are ground waters and springs in arid and semiarid regions (e.g., northern Africa, the American Great Plains and Southwest, Australia). These environments typically support highly endemic invertebrate faunas that are probably very sensitive to human impacts. Throughout much

Box 2 Rivers in the American Southeast

The American Southeast (extending roughly from the Ohio River south to the Coastal Plain of Alabama and Georgia, plus the highlands of Arkansas, Missouri, and Oklahoma) contains ancient river systems with an extraordinarily rich biota (Lydeard and Mayden, 1995; Benz and Collins, 1997; Williams *et al.*, 2008). This region was not covered by Pleistocene glaciers, nor was it covered by the sea or desiccated for hundreds of millions of years, so river systems like the Tennessee, Cumberland, and Alabama (and their associated aquifers) are very old. The rivers and ground waters of the Southeast are examples of biologically rich ecosystems that have suffered badly from human activities.

The freshwater invertebrate fauna of the Southeast contains hundreds of species of mollusks, crustaceans, insects, mites, and other animals (Figure 8) that are found nowhere else in the world. Dozens of genera are known only from this region. Many of these species have small ranges within the Southeast, and may have occurred in only one stream. Despite a long history of scientific study in the Southeast, new species and genera of freshwater invertebrates are discovered regularly in the region.

As is the case for many river systems, the streams and rivers of the Southeast have been deeply affected by human activities. Impoundments have been especially damaging to the invertebrate fauna. All of the large rivers in the region have been extensively impounded for flood control, hydroelectric power, and navigation, to the point that some of the large rivers have been converted into a continuous series of reservoirs. These reservoir systems differ from natural rivers in their hydrology, temperature, chemistry, sediments, and so on, and often are unsuitable for the native riverine biota. Other physical alterations of stream channels, such as channelization, dredging, diking, and instream gravel mining also have severely damaged the freshwater biota in parts of this region. Further, as in most developed countries, southeastern river systems have been badly polluted by toxins, nutrients, and sediments from industries, farms, and cities. Coal is mined in parts of the Southeast, which brings acid mine drainage and fine sediments into streams. Finally, nonnative species, particularly the zebra mussel and biotic exchanges through the Tennessee–Tombigbee Waterway, may affect the southeastern freshwater fauna.

As a result of these massive changes to southeastern rivers, much of the freshwater invertebrate fauna is extinct or imperiled. Among the mollusks, the only group for which reasonably complete data are available, about 60 species and four genera from the Southeast are now extinct. Literally hundreds of additional mollusk species, representing over half of the native fauna, are threatened or endangered. Hundreds of southeastern crayfish and aquatic insects are likewise rare or endangered, and additional species of small, poorly known animals like copepods, isopods, amphipods, and oligochaetes are doubtlessly extinct or at risk of extinction.

The southeastern fauna is now receiving some protection from the US Endangered Species Act and parallel state laws. Nevertheless, unless the continuing damaging effects of human activities like impoundments are reversed or remediated, it is difficult to be optimistic about the long-term prospects for the southeastern freshwater biota.

of the world, humans living in arid and semiarid regions are pumping water out of aquifers faster than it can be replenished, resulting in large, rapid drops in the water table, which in turn dries up springs and aquifers. We know that desert spring communities are endangered (Box 3), and it is possible that aridland aquifers are experiencing large but unseen losses in biodiversity.

In addition to these current threats to freshwater invertebrates, we can expect increasing problems in any regions of rapid human population growth or economic development (e.g., China and southeast Asia), from the wide range of impacts that typically accompany human populations. Further, any rapid changes in climate probably will cause endangerment and extinction of freshwater invertebrates. These climate changes are projected to be most severe in mid- to high latitudes. Because of glaciation, endemism of freshwater invertebrates is higher in midlatitudes than at high latitudes, so impacts of climate change may be most severe at midlatitudes or even in the tropics, especially where the freshwater fauna and environments already have been damaged by human activities. Again, it is the poorly dispersing species that probably will be most severely affected.

There is still no precise answer as to the question of how many freshwater invertebrates actually are endangered (or

extinct) globally. The IUCN estimates likely to be an accurate reflection of actual endangerments only for a few conspicuous and well studied invertebrates (e.g., unionoid mussels, odonates). A reasonable guess might be that 10,000–20,000 of the world's freshwater invertebrate species are extinct or endangered as a result of human activities.

Protection of Endangered Freshwater Invertebrates

Although some freshwater invertebrates are protected by international, national, and local regulations, this protection often is inadequate, for several reasons (New, 1995). First, lists of protected species usually underlist invertebrates and include only the largest, most conspicuous invertebrates. For instance, in the United States, only 120 domestic species of freshwater invertebrates are protected under the Endangered Species Act, all but 29 of them mollusks. Thus, many species of endangered freshwater invertebrates, especially small and inconspicuous animals, are not being protected by existing regulations. Second, simply being listed as a protected species may not provide enough help to endangered invertebrates. In many countries, resources for managing endangered species are insufficient, and attention naturally goes to the larger,

Figure 8 Some endemic freshwater invertebrates from the American Southeast. Clockwise from upper left (with length in parentheses): the flatworm *Sphalloplana holsingeri* (14 mm), the snails *Io fluviatilis* (73 mm), *Gyrotoma alabamensis** (25 mm), and *Amphigyra alabamensis** (2 mm wide), female (50 mm wide) and male (38 mm wide) of the pearly mussel *Epioblasma lewisii**, the copepod *Rheocyclops carolinianus* (0.4 mm), the isopod *Antrolana lira* (20 mm), and the stonefly *Beloneuria georgiana* (22 mm). Species marked* are thought to be extinct.

more charismatic species. In a recent year in the United States, half of all money spent on endangered species was directed to just seven species, all of them vertebrates. As a result, so little money and attention may be spent on invertebrates that plans for recovery of invertebrate species often are general and not pursued aggressively. Third, current approaches to species protection may be inadequate to protect species over the long term. Often, legal protection focuses on trying to prevent further losses from the remaining small populations of an endangered species, without adequate attention to removing the threats that endangered the species in the first place. Consequently, legal protection may slow the rate at which an invertebrate species approaches extinction without reversing its downward trajectory.

How might we more effectively reduce extinction rates of freshwater invertebrates? (Abell *et al.*, 2006; Strayer and

Dudgeon, 2010) First, we need to devise ways to protect species without formally listing them. Human activities will endanger or extinguish many species of freshwater invertebrates before we ever gather enough information on their status to satisfy requirements for legal listing, and before we have enough information on their biology to develop effective species-specific plans to protect them. One way to do this is to take advantage of the fact that many species of endemic freshwater invertebrates co-occur in hot spots by protecting such hot spots from the most damaging of human activities (e.g., dams, excessive water withdrawals, toxic pollution). Such a program of hot-spot protection will require better identification, recognition, and protection of hot spots. Nonetheless, it may require less research and provide more effective protection to the world's freshwater invertebrates than existing species-based programs. Of course, not all endangered species

Box 3 Mound springs of the Great Artesian Basin in Australia

Much of the arid interior of eastern Australia is underlain by a large aquifer called the Great Artesian Basin. Fresh- or brackish-water springs occur along the margins of this aquifer in Queensland, New South Wales, and South Australia. These springs range in size from small, moist seeps to large ($> 100 \text{ L s}^{-1}$), flowing springs, and some of them have built up large ($> 10 \text{ m}$ high) hills of sand and mineral deposits, and so are locally called "mound springs." Although perhaps connected to one another in the past, when the Australian climate was wetter, the springs are now separated from one another by a few meters to many kilometers of desert, and are not connected by streams or rivers.

Like many springs in arid regions, the springs of the Great Artesian Basin support animals that live nowhere else in the world (Ponder, 1986, 1995; Ponder *et al.*, 1989; Ponder and Clark, 1990; Knott and Jasinka, 1998; Perez *et al.*, 2005). Many of these species are found in only one or a few neighboring springs. Only the fish and the snails of these Australian springs have received much study. About 25 species and three genera of snails have so far been found to be endemic to the springs (Figure 9). All of the endemic snails belong to the Hydrobiidae, a widespread family that has produced flocks of endemic species in springs, caves, and ground waters in the Balkans, the arid Southwest of the United States and Mexico, and elsewhere. Although these snails may be very abundant in the Australian springs ($> 1,000,000 \text{ m}^{-2}$), some species are restricted to one or a few springs, and all are highly vulnerable to human impacts. The endemic fauna is thought to have originated by speciation in the more or less isolated springs, perhaps after a more widespread fauna was stranded in the springs by an increasingly arid Australian climate in the Pleistocene.

The chief threat to the spring fauna is from development of wells in the Great Artesian Basin. Because this is an arid region, there is great demand for water for humans, livestock, and mining. When new wells are brought into production, the groundwater level drops, causing springs to dry up. Additional threats include trampling of springs by livestock, which has badly degraded many springs, conversion of springs into pools by excavation or damming, and introduction of non-native species. Over the past three decades, the springs of the Great Artesian Basin have come to be recognized as important habitats for conservation, and steps are being taken to limit at least local impacts from grazing and habitat alterations. Nevertheless, many springs, especially in New South Wales, have dried up as a result of groundwater extraction, and many have been badly altered by livestock or people. It seems likely that at least some of the unique invertebrates of the Great Artesian Basin have gone extinct, and the remaining fauna are at risk of loss.

In arid regions around the world, extreme isolation of aquatic habitats has promoted speciation and development of endemic invertebrate faunas. As in the Great Artesian Basin, water in arid regions is a critically important resource that has been exploited heavily by people. Consequently, freshwater invertebrates of arid regions around the world are endangered by forces similar to those at work in the Great Artesian Basin.

occur in hot spots, so species-based research and protection will necessarily have to accompany any program of hot-spot protection. Further, we could be more aggressive about identifying and removing threats that endanger species rather than just trying to protect the few populations that have somehow escaped threats. This will require creative thinking about how to preserve or restore essential features of habitat without making unrealistic demands on humans.

A second class of possible solutions could be focused on alleviating the dispersal limitations that are so acute for many freshwater invertebrates by actively establishing new populations of endangered species. This class of solutions is motivated by two main concerns. First, simple protection of existing populations of endangered species may fail to assure long-term survival because natural or human-caused catastrophes (e.g., chemical spills) or normal population fluctuations ultimately may take many isolated populations into extinction. Second, it seems likely that global climate change may be faster than the abilities of some freshwater invertebrates to disperse into suitable habitats. To preserve species under these conditions it may be necessary to deliberately establish populations of endangered species in new locations where suitable habitat exists.

This strategy, which is called "assisted migration," has received a lot of attention from conservationists in recent years. However, this strategy has serious problems when applied to freshwater invertebrates because we know so little about these animals (the typical species of endangered freshwater invertebrate in the United States has been mentioned in a total of just one scientific publication!). First, we currently cannot reliably identify "suitable habitat" for most freshwater invertebrates. Second, we do not have good protocols for reintroductions for most species. Third, species introduced outside their native ranges may have unpredictable and undesirable effects on ecosystems and species. Finally, many biologists feel that it is unethical to introduce species outside of their known historical ranges (of course, for many invertebrate species, the known historical range is much smaller than the actual and unknowable historical range). Despite these problems, it may be necessary to confront the problem of species reestablishments, especially if climate change in the twenty-first century is substantial. Clearly, we will need much better information on how fast species are able to disperse in response to a changing climate (to identify which species, if any, will perish without intervention), practical information on how to establish populations of freshwater

Glossary

Anthropogenic Caused by humans.

Depauperate Impoverished, as in a region with low taxonomic diversity.

Endemic Native and restricted to a specific geographic region.

Fossorial Adapted for living or digging underground.

Stochastic event An event that occurs by chance; a random event.

Taxon Any taxonomic group, at any level, that is considered distinct enough from other groups to be considered a separate unit; plural taxa.

Therapsids An order of reptiles that existed during the Late Paleozoic and Early Mesozoic and from which mammals are believed to have evolved.

Mammalian Diversity

Mammals can be found from the arctic to the tropics, on every continent, on many of the smaller islands, and in all of the oceans. There are wholly aquatic mammals (Cetacea), semi-aquatic mammals, terrestrial mammals, arboreal mammals, fossorial mammals, and even aerial mammals (Chiroptera). Mammals fall into three main groups: The monotremes, who lay shell-covered eggs and have a number of physiological structures in common with reptiles, including a single urogenital opening; the marsupials, noted for a suite of physiological traits, including an incomplete placenta, a female bifid reproductive tract, and usually an abdominal pouch for the almost-embryonic young; and the eutherians, who have a chorioallantoic placenta and give birth to relatively precocial young. Mammals may live for more than 100 years, as suspected in some cetaceans, or as short as 1 year, as in the “annual” males of the marsupial *Antechinus*. Mammalian social systems vary from solitary individuals through a wide range of social organizations to the termite-like sociality of the naked mole rat (*Heterocephalus glaber*). Mammals can have individual home ranges as small as a few square meters to systems where groups of tens of thousands migrate together (e.g., wildebeest and caribou) and migrations may cover thousands of kilometers (e.g., gray whales). Mammals have evolved to feed on virtually anything that might qualify as edible, from invertebrates to other mammals, and to fungi, grasses, leaves, bark, and even conifer needles. The variety of niches utilized by mammals and their behavioral and physiological adaptations are enormous – it is difficult to think of a niche not already occupied by a mammal, from aquatic grazer (the Sirenia) to aerial piscivore (*Noctilio* and two other genera of bats).

Not only can mammals be found in most places on earth, but also many species can have dramatic effects on their ecosystems. Classic examples include the alteration of drainage systems and vegetation patterns caused by beaver dams; the alteration of bush and forest to grassland caused by elephant foraging; the alteration of forest pattern and structure caused by sciurid seed predation, hoarding, and burial; and

the alteration of grassland pattern and structure caused by grazing by both large ungulates such as American bison (*Bison bison*) and a suite of African ungulates, and small rodents such as prairie dogs (*Cynomys*) and viscachas (*Lagostomus maximus*). Many of these effects have been shown to increase biodiversity of both plants and animals within the region of modification.

Despite the high visibility and appeal of mammals and their significance to ecosystems, we astonishingly still know little about most species. This is especially true for the smaller, more cryptic, and nocturnal groups, such as the rodents, insectivores, and bats, which make up the bulk of mammalian species diversity, but it is also true for larger, more conspicuous species. Of all known species of mammals, 408 (10%) have been discovered since 1993 (Ceballos and Ehrlich, 2009), although a significant number of those have been ‘found’ through laboratory genetic investigations. New species include small creatures such as rodents and bats, as well as larger species such as monkeys (55 new species), the lesser mouse-deer or Kanchil (*Tragulus kanchil*) (the smallest known deer), and *Prionodiptomus incarum*, a living representative of Diatomidae, a family considered extinct for 11 million years (My). For many of these and other species, there is not even basic information on population size, geographic range, or even whether the species is still extant. For example, in the case of the Asian elephant (*Elephas maximus*), Blake and Hedges (2004) and Hedges (2006) suggest that the global population ‘estimate’ of approximately 40,000 to 50,000 Asian elephants is no more than a guess and what is known about the status of Asian elephants is only the location and relative abundance of some (probably most) populations; in some cases it is uncertain whether populations are still extant.

A Brief History

Early Mammalian History

The history of mammals has been traced back approximately 200–250 million years ago (Ma) to offshoots of the therapsid reptiles in the Triassic. According to limited fossil evidence, the

first major radiation of mammals occurred in the Late Triassic, approximately 200 Ma, and subsequently in the Jurassic. Although the diversity of mammals was increasing at this time, with marsupials and placentals in evidence by the Early Cretaceous, these early mammals tended to have small and fairly uniform body sizes. A number of hypotheses have been generated to explain both the increase in mammalian diversity and the small body size. The breakup and then reattachment of the continents allowed for isolation, speciation, and then faunal exchange, and the development of angiosperm plants also undoubtedly resulted in coevolutionary adaptations and speciation by a wide range of mammals. Small body size perhaps was influenced by the dominance of reptiles, which may have forced mammals into a secretive, nocturnal lifestyle where a small body size would be an advantage. An explosive mammalian radiation occurred in the Paleocene, again partly from repeated separations, isolation, and reintroductions as continents continued their movements, and perhaps further spurred by the loss of a wide range of large reptilian competitors during the great extinction event 65 Ma.

The Pleistocene Extinctions

Between 30,000 and 10,000 years ago, a number of sudden and major die-offs occurred almost entirely among large terrestrial mammals. Between 15,000 and 10,000 years ago in North America, a megafaunal extinction event claimed up to 34 genera of large mammals, including mastodons, mammoths, ground sloths, camels, horses, and various large predators such as saber-toothed cats and dire wolves. A similar extinction event involving 52 genera of mammals occurred in South America between 12,000 and 8000 years ago. In Australia, 14 genera of large mammals disappeared between 50,000 to 32,000 years ago. Debate continues on the causes

for these extinction events. The hypothesis that they are climate change-driven is overshadowed by evidence that megafaunal extinctions have coincided, nearly without exception, with human arrival. This suggests that the answer lies in the realm of a variety of human-caused situations, possibly exacerbated by climate change. They include rapid overharvesting, biological invasions, habitat transformation, and disease.

Recent Mammalian Extinctions

Many island mammal fauna suffered extinction events similar to those that occurred on the continents during the Pleistocene, although most island extinctions occurred in more recent times. On islands in the Mediterranean, 13 endemic genera vanished, including small goats and even dwarf elephants; most disappeared approximately 4000 years ago. A dwarf form of the mammoth disappeared from Wrangell Island approximately 3700 years ago. In Madagascar, eight genera of lemurs, two genera of pygmy hippos, and what is now considered a distinct order, the Bibymalagasia (comprising two species that are variously aligned with the aardvarks and the ungulates), became extinct approximately 1000 years ago. In each of these cases human activity, either hunting, habitat alteration, or a combination, is thought to be the main cause. Island extinction events have continued into modern times. In the Caribbean Islands, five insectivores, 12 rodents, a raccoon, and a seal have all become extinct since 1500 – almost a quarter of all recorded mammal extinctions during that period (Figure 1).

Although the total number of mammalian extinctions in recent times does not appear to be large, the current rate of extinction, approximately 0.01% per year, is anywhere from 100 to 1000 times greater than what would be predicted from

Figure 1 Known mammal extinctions since 1500.

the fossil record, and this rate will very likely increase in the near future. The status of 5488 species of mammals was reviewed in the 2010 IUCN Red List of Threatened Animals. Of those reviewed, approximately 25% were considered at risk of extinction. This percentage is undoubtedly an under-estimate, as the status of many mammal species is still unknown.

Causes and Threats

Many of the dangers that threaten other taxa also threaten mammals. These dangers include habitat loss, exploitation, disease, and exotic introductions, but there are some differences in the manner and level of these threats for mammals as compared to other taxa. For example, human persecution and harvesting pressure is probably greater for mammals than for most other taxa, with the probable exception of fish. True mammalian specialists are rare compared to taxa such as insects, where many species are entirely dependent on only one species of plant and thus are extremely vulnerable to habitat changes that alter community structure. However, many mammals are relatively large, and their habitat needs in terms of area are greater than for most other taxa, putting them at high risk of habitat loss and fragmentation.

A number of historical mammalian extinctions have occurred due to human exploitation or introductions rather than habitat loss. Of 18 mammal species that have become extinct since 1600 and whose cause of extinction is known, eight became extinct due to direct human persecution, eight became extinct as the result of introduced predators and competitors, and only two became extinct because of habitat destruction. At present, many mammalian species are now under a growing threat from habitat changes in addition to direct human persecution. According to the Third edition of the Global Biodiversity Outlook (2010), mammals have suffered the steepest increase in risk of extinction in South and South-East Asia due to the combined impact of hunting and loss of habitat.

Mammalian Physiology and Its Relationship to Threats

Mammals constitute a class of organisms that span an enormous size range of approximately eight orders of magnitude, from 2 g in some bats and shrews to 190,000 kg in the blue whale. However, the majority of mammals tend toward large sizes compared to other taxa, and they tend to have a correspondingly long maturation and slow reproductive rate. This puts them at risk from exploitation and other threats, as breeding rates may not be able to keep up with losses in a population. An extreme example is the blue whale (*Balaenoptera musculus*), whose population has been depleted by at least 70%, and possibly as much as 90%, in less than a century. Despite a halt in whaling that targeted this species in 1966 (identified as the key driver of the decline of the species), the blue whale remains endangered. It has been proposed that its subspecies, the Antarctic blue whale (*B. m. intermedia*), be separately listed as Critically Endangered given the population decline over the same period of more than 97%. Large body size often means large habitat needs, which also puts mammals at risk. Estimates for self-sustaining populations of

carnivores such as brown bears (*Ursus arctos*) and African wild dogs (*Lycaon pictus*) range from 1000 to more than 10,000 km² of suitable habitat, which means that many protected areas are too small to sustain long-term populations of these species. However, for some species it is not simply a question of large habitat. For tigers (*Panthera tigris*) the actual available prey density is a key determinant of tiger numbers – areas such as India that contain high densities of deer, boar, and other prey have tiger densities roughly 10 times that of the Russian Far East, where prey densities are similarly lower (Miquelle *et al.*, 2010; Karanth *et al.*, 2004).

Habitat Loss, Degradation, and Encroachment

Habitat loss and fragmentation is the single greatest threat to biodiversity worldwide, and this certainly holds true for mammals today. Conversion of habitats by humans into other land uses can fragment and separate mammal populations and increase the likelihood of local population extinctions and eventual species extinction. Rapid deforestation of tropical areas is a growing threat to a number of mammalian species, including many large, wide-ranging, or specialist species of primates, cats, and forest ungulates, as well as numerous small species with restricted ranges such as rodents, insectivores, and marsupials. Most of these species cannot adapt to a highly fragmented or altered landscape, and the few that do adapt may come into conflict with humans by feeding on crops or livestock.

The example of the giant panda (*Ailuropoda melanoleuca*) shows some of the complexities related to fragmentation and habitat loss. Pandas feed primarily on bamboo that may live for decades but then tends to flower, seed, and die en masse within certain areas. When this happens pandas must switch to other bamboo species, often having to move to new locations to find these alternative food sources. According to studies following the latest major bamboo die-off in the early 1980s, pandas were still able to survive by finding patches that had not flowered, moving to new locations or switching to other less-favored species of bamboo. The increase in human population within the panda's range in China has now limited most populations of pandas to very small islands of habitat. Widely separated and very small populations of pandas may not be viable over the long term, even without the problems faced from the fluctuations in their food source.

Because mammals are often relatively poor dispersers, the creation of corridors linking habitats has been suggested as a way to help some species, especially large or wide-ranging (including nomadic or migratory) ones. But for many mammals the necessary size and structure of corridors is unknown, and few management plans have yet to put this idea into practice.

Genetic Loss

It is generally assumed that a population's long-term survival is at least partly dependent on sufficient genetic variation for individual fitness and population adaptability. Loss of genetic diversity and reduced fitness from inbreeding depression and the chance fixation of detrimental alleles has been presumed to reduce adaptive potential and increase the probability of

extinction. However, this has been notoriously difficult to quantify and has not yet been proven to have directly caused a decline in a mammal's population in the wild. Other events, such as disease or predation, often complicate analysis, especially as lowered fitness may increase an individual's susceptibility to these factors. There are some examples for which reduced genetic fitness may well be a cause for declines in mammal populations. The genetic bottleneck that occurred in cheetahs (*Acinonyx jubatus*) in the Pleistocene have been associated with increased fluctuating asymmetry in metric skull measurement, relatively low levels of normal spermatozoa in males, immunologically accepted reciprocal skin graphs between unrelated individuals, dental anomalies and palatal erosion, and an increased susceptibility to infectious disease agents. However, since then, cheetah populations have been reconstituting genetic variation, and current levels of cheetah microsatellite variation approach those of several other outbred populations of felids (Marker *et al.*, 2008). Isolation and reduction in numbers leading to inbreeding of Florida panthers (*Puma concolor coryi*) is considered to be the cause of low sperm counts, malformed spermatozoa, and cryptorchidism (undescended testicles), as well as an increase in heart defects within this population. The genetic restoration effort in the 1990s that introduced animals from Texas has shown signs of improving the genetic fitness of the Florida population.

Another potential genetic threat to endangered mammals is hybridization. Documented cases of hybridizations involving endangered species include Ethiopian wolves (*Canis simensis*) with domestic dogs (*Canis familiaris*), and Asian wild asses (*Equus hemionus*) with domestic horses (*Equus caballus*). Hybridization with domesticated forms or relatives is also seen as a threat to wild yaks (*Bos grunniens*), Bactrian camels (*Camelus bactrianus*), Mongolian wild horses (*Equus ferus przewalskii*), and European wild cats (*Felis silvestris*), among others.

Another genetic issue is the loss of native species and their replacement by common generalist species characteristic of human landscapes. This can result in a local numerical increase in species diversity but a worldwide loss of genetic diversity. One example is the introduction of the American grey squirrel (*Sciurus carolinensis*) into the British Isles and Italy and its replacement of the native red squirrel (*Sciurus vulgaris*).

Livestock and Disease

Domestic livestock and their attendant parasites and diseases have had dramatic effects on some wild mammal populations. Land clearing and overgrazing by domestic cattle, sheep, and goats have altered and fragmented landscapes, increased desertification, and reduced forage for other herbivores. The African rinderpest epidemics of the late 1800s, introduced by cattle, devastated a wide range of wild ungulate populations across the continent. More recently, African horse sickness decimated Indian wild asses, canine distemper killed one-quarter of the lions (*Panthera leo*) in the Serengeti National Park, and all eight packs of wild dogs (*L. pictus*) involved in a study in the Serengeti region disappeared in 1991 with rabies as the suspected or confirmed cause. Disease can spread in the opposite direction, with equally problematic results for

wildlife; for example, bison have been shot when they wandered outside of protected areas in the Yellowstone National Park in an attempt to control the spread of brucellosis to cattle. Another example is that of the proposed culling of Mongolian gazelles (*Procapra gutturosa*) in Mongolia to limit the spread of foot and mouth disease outbreaks.

Another factor related to livestock and disease has been the erection of fences to separate wildlife and domestic animals. The results have sometimes been dramatic, such as the case in Botswana, where enormous fences were built in an attempt to control the transmission of disease. These fences blocked the natural migration routes of wild ungulates during the dry season and resulted in the deaths of tens of thousands of red hartebeest (*Alcelaphus bucelaphus caama*), blue wildebeest (*Connochaetes taurinus*), and other antelopes.

Exploitation

Exploitation of mammals has occurred for many different reasons. Subsistence hunting is a growing pressure due to the explosion of the human population, especially in developing countries where much of the populations' dietary protein may come from wildlife. Along with the increase in the human population has come an increase in the number of accurate firearms, including automatic weapons, which are now available to subsistence hunters. Subsistence hunting especially threatens ungulates, such as various deer and tapir species in Asia and South America – more than one third of all deer species and three of the four tapir species are now considered endangered or critically endangered. Subsistence hunting also threatens aquatic mammals whose ranges have already been limited from other causes or who, like sirenians and river dolphins, can primarily be found in coastal or riverine areas. Steller's sea cow (*Hydrodamalis gigas*), the largest and only cold-water sirenian, was hunted to extinction by hungry sailors and other visitors to the north Pacific within 27 years of the first scientific description of this monotypic genus.

Commercial meat hunting has also threatened some species of mammals. The saiga antelope (*Saiga tatarica*), a migratory species of the Central Asian Steppes that once numbered in the millions, was hunted almost to extinction – a nearly 97% decline – in only a few decades. The main threat appears to have been uncontrolled illegal hunting for horns (male horns are exported for the traditional Chinese medicine trade), although habitat degradation and destruction of traditional migratory routes, and hunting for meat in the wake of the break-up of the former USSR in the 1990s, all led to the catastrophic fall in numbers. Recent studies also show that selective hunting of young males and subsequent distortion of sex ratios may have contributed to reproductive collapse.

Until recently the fur trade was an important part of many countries' economies and cultures. In North America, this trade led to the depletion of many fur-bearing species by the early to middle 1800s, including beaver, marten, fisher, otter, and a number of species of seals. Fur hunting for sea otter (*Enhydra lutris*) caused the population of this species to drop from an estimated 300,000 to less than 2000 by 1911, and hunting for skins was the main cause of depletion in numbers for the now-extinct Caribbean monk seal (*Monachus tropicalis*).

More recently, the market for fur has resulted in heavy losses in most wild cat species, including large cats such as tigers and jaguars and the smaller spotted cats of South America and Asia. However, it should be noted that other mammal species, especially wide-ranging, abundant, and fast-breeding species such as the muskrat, raccoon, and coyote, have maintained their numbers despite heavy trapping efforts that continue to this day.

A second result of the fur trade was the introduction of fur-bearing animals outside of their ranges, often with unintended results. The accidental release of American mink (*Mustela vison*) into Europe now threatens the European mink (*Mustela lutreola*), as the American species breeds earlier and appears to be outcompeting its European counterpart.

Commercial hunting is not limited to fur. The hunting of whales for oil as well as baleen led to severe depletions of populations of many species in both hemispheres, with some populations driven to extinction and others lowered to below 5% of their original estimated numbers. Although bans have been in place for most species of whales for some time, many populations have yet to show signs of recovery.

Exploitation for body parts used in traditional medicine has also led to the decline in a number of mammal species. Almost every part of a tiger (*P. tigris*) is used for medicinal purposes, including the feet, fat, bones, blood, testes, penis, bile, whiskers, claws, and tail. The Asiatic black bear (*Ursus thibetanus*) is under great pressure from poaching for its gallbladder, which is used in traditional remedies, and the poaching of rhinos for their horns, which are used both for knife handles and traditional medicines, is the major cause of their precipitous decline. Although habitat loss, trophy hunting, and persecution played an important role in the initial decrease in tigers, bears, and rhinos, poaching for the medicinal market is now the greatest threat to their continued survival.

Persecution

Persecution usually takes the form of purposeful attempts to control or extirpate a species. Examples include persecution of potential livestock predators such as wolves and tigers, potential livestock disease threats such as antelope species in Africa and bison in the Yellowstone National Park, potential livestock competitors such as prairie dogs in the United States, and, in the case of the American bison in the 1800s, an effort to control and eradicate the indigenous human culture that once depended on this large ungulate. In some cases, control efforts have driven nontarget species to endangered status, such as poison control efforts aimed at coyotes that eradicated the swift fox (*Vulpes velox*) throughout much of its range, and the prairie dog eradication efforts that eliminated the rodents more than 98% of their range and drove the black-footed ferret, a predatory specialist on prairie dogs, to the edge of extinction.

Interference

Interference can occur in a number of ways. As mentioned, fences have interfered with migratory ungulates in Africa and

elsewhere. Dams have negatively affected Ganges and Indus river dolphins (*Platanista gangetica* and *Platanista minor*) by fragmenting populations, increasing siltation, and reducing fish prey – and this may have also contributed to the apparent recent extinction of the baiji or Chinese river dolphin (*Lipotes vexillifer*). For the critically endangered North Atlantic right whale (*Eubalaena glacialis*) injuries from boat collisions and entanglement in fishing and lobster gear have accounted for as much as a third of all mortalities in a year, whereas for manatees in Florida boat collisions have accounted for up to a quarter of all mortality in a year. The population of Hector's dolphin (*Cephalorhynchus hectori*), a small coastal species from New Zealand, continues to decline as death from gillnets entanglement exceeds the already low reproductive rate of the species. Spinner dolphin (*Stenella longirostris*) populations were significantly reduced due to drowning by tuna seiners who targeted the species because of their association with tuna schools. In Florida, the greatest cause of mortality for the endangered subspecies of key deer (*Odocoileus virginianus clavium*) and Florida panther is from being struck by cars. Even tourism may pose a threat. For example, tourist vehicle chases in desert environments have led to death from exhaustion of threatened African wild asses (*Equus asinus*) and addax (*Addax nasomaculatus*) in Northern Africa. The expansion of the whale watching industry has led to concerns that the increasing number of boats, motor noise, and chases may negatively affect whale behavior, including disturbing migratory patterns, breeding efforts, and even separating mothers and young.

War is an extreme example of interference, and it can have an equally dramatic effect on already-rare mammal populations. Although there are arguments that historical tribal warfare may have created source buffer zones for large mammal populations (Martin and Szuter, 1999), today's warfare results in numerous negative effects including habitat destruction from defoliation and bombing efforts and the increase in killing of wildlife due to improved hunting efficiency from the availability of modern firearms. This combination is thought to have had an effect on most wild mammals in Vietnam, including the endangered Douc langur (*Pygathrix nemaeus*). Soldiers and guards may also negatively affect wildlife. For example, the disappearance of most of the remaining population of Marco Polo sheep (*Ovis ammon polii*) along the China–Pakistan border is attributed to target practice and trophy hunting by armed border forces. War may also cause local increases in subsistence hunting and habitat destruction by desperate indigenous and displaced people, especially in and around formerly protected areas. This appears to be the case in Ethiopia and Somalia, where rare antelope and wild ass are heavily hunted, and in Western Africa, where mountain gorillas (*Gorilla gorilla beringei*) have been under periodic pressure from human refugees seeking an escape from fighting as well as food and firewood in protected forests.

Pollution

Most documented cases of pollution affecting wildlife relate to taxa other than mammals, such as DDT and peregrine falcons or acidification and brook trout. There are cases where

pollution has had an effect on populations of threatened or endangered mammals. For example, bats in southwestern North America suffered from DDT spraying, and a number of European bats have been affected by wood preservatives used in buildings that serve as roosts. Most documented mammal-pollution relationships, however, have involved aquatic systems. Perhaps the most obvious example was the death of thousands of sea otters from the effects of the Exxon Valdez oil spill in Alaska. Less obvious cases include the St. Lawrence population of beluga whales (*Delphinapterus leucas*) that have been shown to have high levels of organochlorines that have been implicated in cancers, ulcers, infections, and decreased fertility compared to open ocean belugas. Decreased pup production has been noted in seals fed with fish from polluted waters in Europe, and mercury released from mining is thought to pose a serious threat to Amazon river dolphins (*Inia*) and manatees (*Trichechus inunguis*).

Pollution may also have a more subtle effect by increasing a populations' vulnerability to disease by depressing the immune system. Seals have suffered outbreaks of disease in the Mediterranean, northeast Atlantic, and in Lake Baikal. Immune depression has been shown to exist in harbor seals (*Phoca vitulina*) from the Baltic. Pollution is thought to have led to infections from a calicivirus in California sea lions (*Zalophus californianus*) that caused abortion and premature parturition. Dall porpoises (*Phocoenoides dalli*) have been found to have an inverse correlation between serum testosterone level and DDE concentrations in their blubber. Noise pollution, in the form of underwater noise, can affect marine mammals behaviorally and physiologically. In 2000, two minke whales, 15 Blainville's beaked whales (*Mesoplodon densirostris*), and one Atlantic spotted dolphin (*Stenella frontalis*) were stranded in the Bahamas due to noise pollution caused by a US navy exercise, and in 2005, 34 short-finned pilot whales (*Globicephala macrorhynchus*), one minke whale (*Balaenoptera acutorostrata*), and two dwarf sperm whales (*Kogia sima*) died in a similar incident in North Carolina.

Introductions

Introductions of exotics, both purposeful and accidental, have had very strong impacts on some native species of mammals. These impacts may involve predation, competition, and the concurrent introduction of diseases or parasites. Most documented introduction problems have involved mammals as the pest species and have taken place on islands. Cases include the introduction of goats, sheep, and other herbivores to islands where endemic plants lack defenses against herbivory, and the introduction of omnivores such as rats, pigs, and macaques or carnivores such as mongooses and stoats to islands where endemic animals lack defenses against predators. The introduction of rabbits (*Oryctolagus cuniculus*) to Laysan appears to have driven three species of birds to extinction from grazing that destroyed avian food sources, both plants and insects dependent on the plants. The results from the explosive population growth of rabbits introduced into Australia are well documented, although predation by nonnative red foxes probably has had a greater negative effect on indigenous small

marsupials. Both pet and feral cats and dogs also pose a threat to wildlife. Feral cats in Australia are estimated to kill more than 400 million native mammals, birds, and reptiles each year, whereas in Argentina, predation by dogs is the biggest threat to the endangered pink fairy armadillo (*Chlamyphorus truncatus*). Introduced aoudad (*Ammotragus lervia*) and feral burros in the Southwest United States are considered to be potential competitors and disease vectors for the desert big-horn sheep (*Ovis canadensis nelsoni*). Introduced deer species have had major effects on vegetation in New Zealand, and in South America they may be serious competitors of the endangered Andean huemul (*Hippocamelus bisculus*).

Multiple Threats

For many species, a series or combination of the factors listed has led to precipitous population declines and endangerment. For the tiger, trophy hunting, eradication programs, market exploitation for fur and traditional medicines, and loss of habitat all played a role in the extinction of three races and a decline from perhaps more than 100,000 tigers worldwide in 1920 to as few as 3200 today.

Even for mammals that have recovered from previous threats, new factors may arise to threaten the species. The saiga antelope recovered from commercial hunting once a ban and then regulations were put in place, rebounding from a low of only a thousand in the early part of the last century to more than 2 million in just 50 years. However, poaching for medicinal products, overgrazing, desertification, and migratory barriers now threaten the species, and the population has dropped to around 60,000 animals in five widely separated regions.

Locations for Endangered Mammals

Geographic Analysis of Endangered Mammals

As with most other taxa, mammalian species diversity tends to increase with decreasing latitude. The top eleven countries for mammalian diversity are Indonesia (670), Brazil (648), China (551), Mexico (523), Peru (467), Colombia (442), United States (440), Democratic Republic of Congo (430), India (412), Kenya (376), and Argentina (374). Only the USA is not found entirely or primarily within the tropical zone. The number of threatened mammals is shown in **Table 1**, with Indonesia leading the list with 183 and Mexico following with 100. Most of the listed countries also have some of the highest human densities in the world. However, some of these countries, such as Australia, have high numbers of threatened species yet relatively low human densities. In most of these cases a second factor, endemism, can explain much of the data.

Endemism: The Case of Australian and Island Mammals

Oceanic islands tend to have depauperate mammalian faunas, primarily because terrestrial mammals make poor oceanic dispersers. Many islands also do not have enough habitats to maintain viable populations of terrestrial mammal species.

Table 1 Countries with the most species of threatened (CR, EN, VU) mammals

	<i>Number of threatened mammals</i>	<i>Total number of mammals in country</i>	<i>Percent threatened</i>	<i>Total number of threatened endemics</i>
Indonesia	183	670	27	115
Mexico	100	523	20	80
India	96	412	23	31
Brazil	82	648	13	55
China	74	551	14	17
Malaysia	70	336	21	6
Madagascar	62	228	29	57
Thailand	57	311	19	1
Australia	55	349	22	50
Vietnam	54	359	12	19
Peru	53	467	15	27
Colombia	51	442	19	3
Lao People's Democratic Republic	46	215	21	3
Myanmar	45	294	15	0
Ecuador	43	372	12	14
Cameroon	41	335	12	14
Papua New Guinea	41	269	15	24
Philippines	39	209	19	27
Cambodia	37	164	23	0
United States	37	440	9

However, on islands that terrestrial mammals were able to colonize, and that were large enough to sustain populations, isolation often led to speciation. Some examples of island endemism are truly spectacular, and often these locations also contain some of the most threatened species in the world. Indonesia, an archipelago consisting of more than 13,000 islands, has the greatest species richness in the world and also has the greatest number of endemic mammal species with 115. Indonesia also has the greatest number of threatened mammals with 183 (27% of its mammalian fauna). In Australia, out of a total of 349 species of mammals, 247 species are considered endemic. Twenty-one species are recorded as extinct since 1500 and, of the remaining species, 55 (22%) are considered threatened with extinction. Madagascar is the fourth largest island in the world and has been separated from mainland Africa since the Cretaceous. Because of its long isolation, all but one of the terrestrial species are endemic forms (the exception is a pig that may have been introduced). There are five families and 15 genera of living endemic primates (the lemurs), an endemic family of insectivores (the Tenrecidae), three endemic subfamilies of the carnivore family Viverridae, at least eight endemic genera of rodents, and a family of bats (the Myzopodidae). Of the endemic species, 57 (31%) are currently threatened, many from the recent loss of 80% of the island's original forest cover. Papua New Guinea has 269 species of mammals, of which 73 are endemic; 41 species are also considered threatened. In the Philippines, more than half (113 out of 207) of the mammal species are endemic, and 27 of these are considered threatened. As mentioned, many of these islands have already suffered extinction spasms: Of a total of 102 mammal species recorded as extinct since 1500, 65 are from islands, of which 21 occur in Australia.

Which Mammal Taxa are Most Threatened?

IUCN Red Data Book

Lists such as the Red Data Books are useful in drawing attention to the plight of certain species and in developing conservation and management efforts, including the creation of protected areas. The 2010 IUCN Red List of Threatened Animals attempted to assess the conservation status of every mammal species in the world. Each species was placed within one of eight categories. The first three are categories of threat: critically endangered, endangered, and vulnerable. The next three are lower risk categories: conservation dependent, near threatened, and least concern. The last two categories are data deficient and not evaluated. As well as these categories, two more exist: extinct and extinct in the wild. Out of a total of 5488 species of mammals whose status was reviewed by IUCN, 22% were considered to be globally threatened or extinct. 15% have insufficient data to determine their threat status (Figure 2). This compares with 12.5% of birds globally threatened, with less than 1% data deficient. A possible explanation for why 22% of mammals are under direct threat as compared to only 12.5% of birds is that mammals are not as efficient dispersers. Birds in general are more likely to be found over a wide area, and as habitats become fragmented or disappear some populations are likely to survive, and individual birds can also move to new locations more easily than mammals.

The development of programs such as national Red Data Books that cover individual countries or the Natural Heritage Data Centers that cover North and most of Central America has led to a new spatial scaling of endangerment. These local lists often list many more species and subspecies of mammals

Figure 2 IUCN red list of threatened mammals (2010) showing the categories: data deficient, extinct and extinct in the wild, critically endangered, endangered, vulnerable, near threatened, least concern.

than appear in the IUCN Red Data Book. This is both from inclusion of species that are locally but not globally endangered and endemic subspecies that have yet to receive international attention. The inclusion in a national or regional list of an otherwise-common species whose range barely reaches the borders of a country, may at first seem questionable. However, there is the likelihood that it is a genetically distinct subpopulation adapted to living in what would otherwise be considered marginal habitat for the species.

Endangered Mammals by Taxa

An analysis of endangered mammals by taxa, using the IUCN Red List categories and criteria (2010), shows that among the larger orders of mammals primates are the most endangered, with 49% of the species under threat (critically endangered, endangered, or vulnerable). All primate species are either on Appendix I or II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Primate threats are many and varied, but the principal threat is habitat destruction. Because most primates have arboreal habits, tropical forest loss and fragmentation have had strong negative effects. Captures for the pet trade, zoos, and medical research had a major impact on a number of species until recent legislation limited wild captures. Other species have been affected by subsistence hunting or accidental take from snares set for other species.

Only four other orders have a higher percentage of threatened or extinct species: Sirenia (manatees and dugongs) (100%), Perissodactyla (odd-toed hoofed mammals, such as horses, tapirs, and rhinos) (81%), Monotremata (like platypus and echidna) (60%), and Proboscidea (elephants) (50%); however, these four orders have only five, sixteen, five, and two

species, respectively. Two other orders with more than 100 species and a significantly higher than average level of threat are the Cetartiodactyla (whales, dolphins, and even-toed ungulates) (35.9%) and Diprotodontia (marsupials) (35.6%). Although much attention has been given to threatened members of the order Carnivora, “only” approximately one-quarter (26.7%) of the species are threatened. Rodents have approximately 17.5% of species listed as threatened (although comparatively little conservation research has focused on the status of rodent species), but because of the relatively large number of rodent species this order has the highest number of species under threat with a total of 358.

Conservation

Conservation Legislation

An enormous number of treaties and laws govern protection for wildlife or their habitat. These measures include prohibitions or controls on taking, collection, possession, and trade of specific species, control of exotic species, and the protection of habitat, either directly through the creation of protected areas or through indirect measures such as tax incentives, permits, and zoning.

Three levels of conservation legislation exist. The first is multilateral treaties, involving conservation of habitat as in the Convention of Wetlands of International Importance known as RAMSAR, international trade as in CITES, conservation, sustainable use and access and benefit sharing of biodiversity as in the United Nations Convention on Biological Diversity (CBD), and the conservation of terrestrial, avian, and marine migratory species as in the Convention on Migratory Species of Wild Animals (CMS). The second is regional treaties, such as the Bern Convention on the Conservation of European Wildlife and Natural Habitats. The last involves bilateral agreements, such as the 2000 USA and Russia agreement for the long-term conservation of shared polar bear populations in Alaska, in the USA, and Chukotka, in Russia.

Among the multilateral treaties, CITES is especially important for conservation of endangered mammals. CITES was established in 1973 to deal with the enormous level of international trade in wildlife, with estimated earnings of more than US\$20 billion. CITES has three appendices, with Appendix I listing species threatened with extinction, Appendix II listing species that may become threatened with extinction unless trade is regulated, and Appendix III listing species protected under national law. Unfortunately, a treaty is only as good as the on-ground enforcement of its provisions, and while CITES has gone a long way toward stemming the tide of illegal trade in wildlife, black market commercial exploitation continues to threaten many species throughout the world.

Species Survival Commissions (SSC)

The International Union for the Conservation of Nature (IUCN) is an intergovernmental organization that counts as members government and nongovernment organizations and volunteer scientists dedicated to the conservation of

biodiversity, primarily through monitoring and advisory roles. IUCN now has more than 100 specialist groups within the Species Survival Commission SSC, each focused on a particular taxa. More than 30 of the specialist groups work on mammals, ranging from multiple orders such as the Afrotheria Specialist Group to individual species such as the Polar Bear Specialist Group. SSC specialist groups consist of volunteer scientists and other experts who provide information on their taxa and even lobby governments for conservation and research efforts. One method of providing this information is through Status Surveys and Conservation Action Plans that describe trends, threats, and conservation options, which most specialist groups have now published for their particular taxa.

Protected Areas

With human population increasing and unmodified habitat rapidly dwindling, habitat protection and maintenance is certainly the single most important conservation method for the preservation of biodiversity, including mammals. Large mammals often live at low densities and over large individual areas. A few protected meadows with the appropriate plant species may be enough habitat to maintain a population of butterflies, but an enormous tract of wilderness is necessary to sustain a viable population of tigers or rhinos. Sadly, many large mammals, such as rhinos and tigers, are now entirely or mostly found within park boundaries, and it is uncertain whether populations are large enough to maintain themselves in the face of stochastic events and anthropogenic changes. Mammals within protected areas often come into conflict with people sharing the land or living on the edges of the protected areas, and poaching may continue to cause declines in mammal populations within protected areas for a variety of social or economic reasons. With climate change, there also exists the possibility that protected areas currently designed around maintaining particular types of habitat will have those habitats altered due to changes in temperature or precipitation, reducing their efficacy for certain species. A new focus on conservation of threatened mammals on the edges of protected areas faces daunting challenges from multiple use, social, cultural, and economic growth issues. However, targeting conservation efforts on the edges of protected areas by engaging local communities may be the only hope for some mammals, as the money and political will to continue creating protected areas is limited.

Captive Breeding and Reintroduction

Captive breeding has become a well-accepted way of managing and increasing populations of critically endangered species. New techniques have led to breakthroughs in captive breeding with some species, including the use of extra-specific surrogate mothers and embryo manipulation, including transfer, cryo-preservation, and microsurgical division. However, captive breeding has not worked in every case. For example, the critically endangered Sumatran rhino (*Dicerorhinus sumatrensis*) has been bred in captivity only after many years of unsuccessful attempts, and the loss of 32 of the original 40 captive animals.

A number of captive breeding programs have led to reintroduction efforts for mammals that were extinct in the wild, including wisent (*Bison bonasus*) in Europe, Arabian oryx (*Oryx leucoryx*) in Oman, and Père David's deer (*Elaphurus davidianus*) in China. Other reintroduction programs have attempted to supplement decreasing wild populations; for example, one third of wild golden lion tamarins (*Leontopithecus rosalia*) are now from captive-bred stock. Perhaps the best-known case of captive breeding and reintroduction of a mammal involves the black-footed ferret (*Mustela nigripes*). This small carnivore was once common across the North American plains, where it specialized in hunting large, colonial ground squirrels called prairie dogs (*Cynomys*). Prairie dogs were considered to be pests and competitors with cattle, so an intensive eradication program eventually reduced historic prairie dog range by 98%. The black-footed ferret subsequently declined and was thought to be extinct in the wild in the 1970s, although a small number of ferrets still existed in captivity. This captive colony suffered from physical problems, perhaps related to inbreeding as well as disease, and the colony died out in 1979, leading to fears that the species had truly gone extinct. However, in 1981 a new colony of ferrets was discovered in Wyoming. The first six ferrets to be captured for breeding died of canine distemper. The remaining wild ferrets were captured and successful captive breeding resulted in their numbers reaching approximately 300, with some released back to the wild. However, the program has not been without criticism: Politically motivated decisions and arguments between state, federal, and private organizations have caused numerous problems and may have even jeopardized the success of the project at times. Finding suitable prairie dog colonies (both in terms of finding colonies of adequate size and the political difficulty of maintaining large numbers of what many consider to be a "pest" species) for continued reintroduction is yet another roadblock to ferret recovery.

Another successful and controversial example has been the reintroduction of gray wolves (*Canis lupus*) into the Rocky Mountain region of the USA in 1995 on Forest Service lands in Central Idaho and in 1996 in the Yellowstone National Park. The reintroduced wolf population, numbering more than 1500 in the Northern Rockies of Montana, Wyoming, and Idaho, has had an obvious effect on the ecosystem, causing a decrease in some species (i.e., coyotes, through competition and killing) and an increase in other species (due, at least in part, to an increase in carrion from wolf kills, but also from ripple effects related to changes in elk habitat use and distribution). This reintroduction has not been without controversy, partly stemming from wolf predation on livestock. In 2009, during a single attack on a ranch in Montana, wolves killed 122 sheep, surpassing the number of sheep killed by wolves in the entire state in 2008.

Other predator reintroduction attempts have not fared so well, however. Attempts to reintroduce lynx (*Lynx canadensis*) in the Adirondacks of New York have failed. The decision by French authorities not to augment the population of brown bears reintroduced in the Pyrenees Mountains of France amidst a hostile social context is casting doubt on the long-term viability of the bear population. The success of many reintroductions has also been threatened by legal challenges from individuals or organizations opposed to land-use

restrictions or worried about potential direct conflicts with humans or livestock.

Reintroductions do not always involve captive breeding. A number of African antelope and Eurasian Caprinae have been successfully translocated from still-viable populations into areas where they had been eradicated. One issue regarding this technique is whether there was a distinct local genotype. This is a serious problem if translocations are being considered as a method to bolster an existing but declining or no-longer-viable population, in which case mixing genotypes may result in the swamping of possible adaptive differences. However, in the case of the Florida panther, the controversial program to mix Texas cougars (*Puma concolor stanleyana*) with the Florida panthers has apparently boosted survival of the species: A study shows that hybrids between the two subspecies are three times more likely to survive until adulthood than purebreds, and adult female hybrids survive longer than adult female purebreds (Pimm *et al.*, 2006). There have also been introductions into areas that were not part of the original range of a species, with occasional unintended results of competition with indigenous species and habitat destruction. In one example, 11 Bahamian hutias (*Geocapromys ingrahami*), an endangered rodent, were introduced to a nearby island in a successful attempt to establish a second population of the species. However, it appeared that the hutia had not lived on this second island at least within historic time, and after 16 years the population had expanded to the point where seven plant species had vanished from the island due to overgrazing.

Reintroductions are a complex undertaking, involving a solid understanding of the biology of the species, from feeding and breeding to individual and population genetics. The animals must be trained to survive in the wild, from finding food to socializing, and in the case of arboreal primates, even learning to move through the trees properly. The location for reintroduction should be part of the original range, be large enough to sustain a viable population, contain the correct habitat specifications, and no longer have whatever pressures resulted in the original loss of the species in the wild. They must be free of disease before being released. Introduced animals must be closely monitored, and there must be strong political and local support and extended funding for the project. Thus captive breeding and reintroduction may only be appropriate in specific cases where this kind of information and support is available.

Economic Incentives

Because protected areas only cover less than 13% of the earth's surface, and captive breeding and reintroductions are only feasible for certain well-studied and well-funded species, other methods will be necessary to ensure the survival of a number of mammal species. One method is economic utilization, which applies the fact that mammals have always been heavily exploited. It also has the important potential advantage of paying for itself. Because much of the present extinction crisis of mammals has an economic incentive, this idea has won wide if cautious acceptance, although controversy still exists on issues such as lack of data on population numbers and

dynamics, whether overuse is inevitable, and concerns over animal welfare.

Sports and trophy hunting has been linked with historic declines in a number of mammal species, often in conjunction with other factors such as habitat loss. However, sports and trophy hunting is being considered as a management tool today. For some species, especially big game animals, it is suggested that conservation can "pay for itself" when fees from hunters are redirected back into management. This can be most effective for polygynous species where males are not a limiting resource and are also considered desirable as trophies. Licensing and management for white-tailed deer in North America has resulted in a population explosion of that species to the point where it is now necessary to actively control deer as pests in many locations. Trophy hunting fees may also be directed back to local communities to help replace losses from subsistence hunting or nuisance animals and encourage conservation awareness and behavior. Wild goat trophy hunting programs in the mountains of Northern Pakistan have resulted in locally effective conservation efforts on behalf of populations of ibex (*Capra ibex*) and markhor (*Capra falconeri*) – with trophy markhor going for up to US\$80,000 an individual, and laws stating that 80% of fees must go back to local communities. In Zimbabwe, the Communal Areas Management Programme for Indigenous Resources (CAMPFIRE) has had success with trophy hunting as an economic incentive for local people to manage their wildlife in a sustainable manner. However, sports hunting as a management tool is only possible when populations of the target species are large enough to support regular culling, monitoring of the target species is constant, regulations are capable of being altered if necessary, and where the political situation enables funds generated from hunting fees to be returned either directly to continued conservation efforts or to local people to encourage their support. From the biological side, potential problems associated with the removal of dominant males include skewed sex and age ratios, lowered genetic variability, altered behavior of other group members, and even the destruction of group cohesion in some targeted species, such as big-horn sheep (*Ovis canadensis*) and elephants (*Loxodonta africana*).

Tourism is another method of raising funds so that the organism under protection pays for itself. This has worked well for a few charismatic species, such as mountain gorillas, but the vast majority of threatened mammal species are not capable of generating a level of public interest that will result in tourism revenues. However, it has been argued that certain charismatic species may act as "umbrellas" to create protection that will cover other species.

Umbrella Species: The Case for and Against Charismatic Megafauna

The umbrella principle of conservation involves the protection of a large or wide-ranging species in the hopes that this will result in the protection of a number of other, smaller species. This concept has numerous advantages: It is easier to mobilize public interest toward large and charismatic species, it is easier to get funding for conservation work, and efforts to conserve large species are likely to result in conservation of

large numbers of smaller species, due to the large habitat needs of the large species overlapping or including those of smaller ones.

The tiger is often used as an example of a species where conservation success will likely mean protection for a number of other species. However, the 38 reserves set up for tigers in India, and four more approved to be set up, have not even adequately protected tigers, and poaching and encroachment threatens the ability of these reserves to protect many other species found within them. Another problem associated with the concept of mammalian umbrella species is that areas of species richness or endemism for other taxa, such as invertebrates, may not be within the designated core area of protection for a large mammal. A third issue of concern is that focused conservation management for a single species, such as antipoaching efforts for tigers, may not satisfactorily protect other species whose main threats may involve other factors such as fire, fragmentation, or the spread of exotic species.

Present and Future Trends

Although mammals get a disproportionate amount of attention and funding for conservation efforts, the future for many species still looks grim. As of 2010, one-fifth of all mammal species were considered to be globally threatened or extinct. For a number of these mammals, a long-term commitment will be needed scientifically, financially, and politically if they are to survive. However, species-based conservation efforts for mammals can have enormous costs. The conservation of the northern subspecies of the white rhino (*Ceratotherium simum cottoni*) was estimated to run approximately US\$10,000 a year per rhino, which was not enough to save the population given that the last four rhinos left in the wild have apparently been poached to extinction. Another example is the cost over 7 years for reintroduction of the golden lion tamarin estimated at more than US\$1.5 million. The cost of creating and maintaining a protected area that will preserve populations of many mammal species (as well as other taxa) is only a fraction of that needed for species-based management.

Unfortunately, for many endangered mammals there is a desperate need for immediate and focused management efforts. There also is a tremendous need for more protected areas and better protection within the protected areas themselves, and a need for directing conservation efforts toward non-protected areas by mainstreaming wildlife conservation concerns into land-use planning. For this to succeed, efforts must also be directed toward engaging and educating local people about conservation issues; minimizing wild mammal–people conflicts by deploying conflict mitigation measures and

promoting the design of creative insurance schemes and policy changes to stimulate incentives for people to coexist with wildlife; and managing the threat of disease transmission. In addition, illegal wildlife trade, one of the key culprits for mammalian decline, must be curtailed through better enforcement and cooperation and by eliminating the demand for endangered mammal products. In all cases, research and monitoring of wildlife populations and threats is critical, especially in situations where sustainable harvesting is being attempted.

Endangered Marine Invertebrates

James T Carlton, Williams College and Mystic Seaport, Mystic, CT, USA

Published by Elsevier Inc.

Glossary

Ecotone The transitional region between two habitats or environments.

Keystone A species with a critical regulatory role (often disproportionate to its abundance) in a community.

Planktotrophic Feeding on plankton by invertebrate larvae to survive and grow.

Stenotopic Occupying a highly specialized habitat or tolerating a narrow range of environmental conditions.

Supralittoral The portion of beaches, rocky shores, and other marine habitats that typically lies above the high tide.

We do not know how many ocean species have gone extinct in historical time. Thus, not surprisingly, we have only a very rudimentary concept of how many species are endangered, threatened, or vulnerable, as defined below (*see* Endangerment – Definition and Tables 2, 3, 4, and 5). This said, thousands of marine invertebrates alone may be at risk of extinction due to a plethora of human-induced pressures, including physical habitat destruction, water quality, and climate change.

Endangerment – Definition

One set of internationally recognized definitions (IUCN, 2011) treats *endangered* and *vulnerable* taxa under the broad category of *threatened* species. *Critically Endangered* species face an “*extremely high risk of extinction in the wild*”. *Endangered* species are at a “*very high risk of extinction in the wild*”. *Vulnerable* species are “*considered to be facing a high risk of extinction in the wild*” (IUCN, 2011). To attempt to apply quantitative boundaries to these otherwise seemingly hazy categories, a series of criteria have been erected based on the observed or projected changes in population size, the geographic range of a species, estimated population sizes, and an overall assessment of the probability of extinction (Table 1).

Data required to populate these fields include temporal data (e.g., rate of population decline and population fluctuations), spatial data (extent of occurrence and number of populations), and population data (size and number of adults).

In the USA, the federal Endangered Species Act (ESA) defines endangered as a species “in danger of extinction throughout all or a significant portion of its range” and threatened as “likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range” (Environmental Protection Agency, 1973).

Although International Union for Conservation of Nature (IUCN) (and other) definitions focus on global extinction, there are other scales of endangerment as well. These include:

- Local endangerment, when a species faces extinction within a region, as in within a bay or estuary, or from a habitat.

- Regional endangerment, when a species faces extinction in a broad region, such as a biogeographical province.
- Functional endangerment, when a species that was performing a keystone or engineering role (as a competitor, predator, parasite, pathogen, or disturbing agent) in a community becomes so rare that it no longer operates to influence the system structure.
- Commercial endangerment, when a species which is the focus of a fishery becomes so rare that it is no longer economically feasible to hunt it.

It may be noted that certain species that are trade protected under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES, 2011) may, by virtue of the convention name, be categorized as endangered species. Species that are the “most endangered” are listed in CITES Appendix I (“all species threatened with extinction, which are or may be affected by trade”); species that “are not necessarily now threatened with extinction, but may become so unless the trade in specimens of such species is subject to strict regulation to avoid utilization incompatible with their survival” are treated in CITES Appendix II. Marine invertebrates are treated only under Appendix II and include the mussel *Lithophaga lithophaga*, giant clams in the family Tridacnidae, the queen conch *Strombus gigas*, black corals (Antipatharia), the blue coral *Heliopora coerulea* (Helioporacea), stony corals (Scleractinia), organ-pipe corals (Tubiporidae), fire corals (Milleporidae), and lace corals (Stylasteridae). Although these taxa may thus be referred to as endangered under CITES, many (such as numerous stony coral species) might not be so listed under IUCN or ESA definitions.

Causes of Endangerment and Examples of Endangered Species

Numerous studies in the 1990s and 2000s (e.g., Pew Oceans Commission, 2003; U.S. Commission on Ocean Policy, 2004) defined five general drivers of human-mediated pressures on marine biodiversity: fisheries activities (both overextraction and the mechanical means by which the target species are collected), habitat destruction, changes in water quality, introduction of nonnative species, and climate change.

Table 1 IUCN criteria for critically endangered, endangered, and vulnerable species

Criteria	Critically Endangered (CR)	Endangered (EN)	Vulnerable (VU)
<i>(A) Reduction in population size</i>			
Based on:			
(a) direct observation			
(b) an index of abundance appropriate to the taxon			
(c) a decline in area of occupancy, extent of occurrence, and the quality of habitat			
(d) actual or potential levels of exploitation			
(e) the effects of introduced taxa, hybridization, pathogens, pollutants, competitors, or parasites			
<i>Past</i>			
1. Observed, estimated, inferred, or suspected population reduction (OEISPR), where the causes of reduction are clearly reversible, understood, and have ceased;	>90% over the last 10 years or 3 generations ^a	>70% over the last 10 years or 3 generations ^a	>50% over the last 10 years or 3 generations ^a
2. OEISPR, where the reduction or its causes may not have ceased, or may not be understood, or may not be reversible;	>80% over the last 10 years or 3 generations ^a	>50% over the last 10 years or 3 generations ^a	>30% over the last 10 years or 3 generations ^a
<i>Future</i>			
3. Population reduction projected or suspected to be met;	>80% within the next 10 years or 3 generations ^a (up to 100 years maximum)	>50% within the next 10 years or 3 generations ^a (up to 100 years maximum)	>30% within the next 10 years or 3 generations ^a (up to 100 years maximum)
<i>Past and future</i>			
4. OEISPR where the time period must include both the past and future, and where the reduction or its causes may not have ceased, or may not be understood, or may not be reversible	>80% over the last 10 years or 3 generations ^a (up to 100 years maximum in the future)	>50% over the last 10 years or 3 generations ^a (up to 100 years maximum in the future)	>30% over the last 10 years or 3 generations ^a (up to 100 years maximum in the future)
<i>(B) Geographic range</i>			
Based on at least 2 of the following 3 criteria:			
(a) Severely fragmented or known to exist at only:	1 location	Maximum of 5 locations	Maximum of 10 locations
(b) Continuing decline, observed, inferred, or projected, relative to extent of occurrence; area of occupancy; area, extent, and quality of habitat; number of locations or subpopulations; or number of mature individuals			
(c) Extreme fluctuations in extent of occurrence, area of occupancy, number of locations or subpopulations, or number of mature populations			
In the form of B1, B2, or both:			
B1 Extent of occurrence	< 100 km ²	< 5000 km ²	< 20,000 km ²
B2 — Area of occupancy	< 10 km ²	< 500 km ²	2000 km ²
<i>(C) Population size relatively small</i>			
Based on:			
Number of mature individuals	< 250	< 2500	< 10,000
And either:			
1. Estimated continuing decline	at least 25% within 3 years or 1 generation ^b	at least 20% within 5 years or 2 generations ^b	at least 10% within 10 years or 3 generations ^b
Or:			
2. Continuing decline, observed, projected, or inferred, in numbers of mature individuals and at least one of the following two:			
(a) No subpopulations estimated to contain:	> 50 mature individuals, or at least 90% of mature	> 250 mature individuals, or at least 95% of mature	> 1000 mature individuals, or all mature individuals are in one subpopulation

(Continued)

Table 1 Continued

Criteria	Critically Endangered (CR)	Endangered (EN)	Vulnerable (VU)
	individuals in one subpopulation	individuals in one subpopulation	
(b) Extreme fluctuations in number of mature individuals			
(D) Population size very small or restricted			
Number of mature individuals	<50	<250	<1000
Population with a very restricted area of occupancy or number of locations, such that it is prone to human activities or stochastic events within a very short period of time in an uncertain future, and is thus capable of becoming CR or even EN in a very short time period			Area of occupancy: <20 km ² Number of locations: <5
(E) Probability of extinction			
Probability of extinction in the wild	At least 50% within 10 years or 3 generations ^b	At least 20% within 20 years or 5 generations ^b	At least 10% within 100 years

^aWhichever is longer.^bWhichever is longer, and up to a maximum of 100 years in the future.Source: Extracted and reorganized from IUCN (International Union for Conservation of Nature) (2011) *The IUCN Red List of Threatened Species*. <http://www.iucnredlist.org/> (accessed November 2011).**Table 2** Marine invertebrates classified as threatened or endangered under the U.S. Endangered Species Act

Species	Category (date listed)	Range	Population status	Threats
<i>Haliotis cracherodii</i> (Black Abalone)	Endangered (2009)	Northern California to Mexico	"Locally extinct" in most areas south of Point Conception CA	Abalone diseases, overextraction (historical), climate change, habitat loss
<i>Haliotis sorenseni</i> (White Abalone)	Endangered (2001)	Southern California to Mexico	99% reduction in density since 1970	Overextraction (historical); population reproduction failure
<i>Acropora cervicornis</i> (Staghorn coral)	Threatened (2006)	Florida to Venezuela, including Caribbean	Declines up to 98% throughout range	Coral diseases and climate change, including increased hurricane activity?
<i>Acropora palmata</i> (Elkhorn Coral)	Threatened (2006)	Florida to Venezuela, including Caribbean	In many areas, 90–95% reduction in abundance since 1980	Coral diseases and climate change, including increased hurricane activity?

Source: Reproduced from Environmental Protection Agency (1973) *Endangered Species Act*, 16 U.S.C. § 1531 et seq. <http://www.epa.gov/lawsregs/laws/esa.html> (accessed November 2011).

The state of our knowledge on how these phenomena and processes impact on an individual basis, let alone their interactions, on any given species, is such that it is often difficult to determine a single major cause of decline for species widely recognized as threatened (Tables 2 and 3). Human-mediated impacts that are the primary cause of endangerment include habitat destruction and fisheries impacts. That said, whether the modern-day surge of critical diseases that have impacted some of the most important reef corals of the Caribbean and the Florida Keys, an abalone disease in California, or stronger and more frequent hurricanes in the Western Atlantic are linked to human-mediated climate change remains unknown (and thus are often discussed without reference to their possible anthropogenic roots), thus potentially obfuscating the overall role of human perturbation. Nevertheless, the possibility that climate change (including coastal warming and ocean acidification) and introduced species may play critical roles in the future in species' endangerment appears clear.

Table 2 presents only four of the threatened and endangered marine invertebrates currently listed under the ESA

by the US National Marine Fisheries Service (NMFS) (NMFS, 2011) and the US Fish and Wildlife Service. Table 3 presents the 11 species considered "critically endangered" on the IUCN "Red List" (three of these overlap with the ESA list; one US species, the "critically endangered" coral *Porites pukoensis*, is not so recognized as even a species of concern by NMFS). In all cases, threats are either referenced generically, unweighted multiple threats are cited, or no threats are noted at all, further underscoring challenges in clearly understanding (and predicting) the demise of even those few species that are on higher profile radars.

IUCN lists other marine invertebrates as either endangered or vulnerable: one of these is the North American Pacific coast abalone *Haliotis kamtschatkana*, listed as "endangered," but, like *Porites pukoensis*, not so recognized under US law (and, indeed, not recognized under any category, including "candidate" or "species of concern"). Not appearing on IUCN lists, or any general lists of endangered species, is the Galapagos seastar *Heliaster solaris*, last seen in 1977. A commensal pea crab, *Enigmatheres canfieldi*, likely collected intertidally from a

Table 3 Marine invertebrates listed as critically endangered by the IUCN

Species	Location	Habitat
Polychaeta		
<i>Mesonerilla prospera</i>	Bermuda	Marine caves
Cnidaria		
Stony corals		
<i>Acropora cervicornis</i>	Western Atlantic	Nearshore reefs (see Table 2)
<i>Acropora palmata</i>	Western Atlantic	Nearshore reefs (see Table 2)
<i>Rhizopsammia wellingtoni</i>	Galapagos Islands	Nearshore reefs (not seen since 2000; possibly extinct)
<i>Tubastraea floreana</i>	Galapagos Islands	Nearshore reefs (not seen since 2004)
<i>Porites pukoensis</i>	Hawaii (Molokai Island)	Nearshore reefs (known from less than 50 colonies)
<i>Siderastrea glynni</i>	Panama (Uraba Bay)	Nearshore reefs
Fire coral		
<i>Millepora boschmai</i>	Panama	Nearshore reefs (possibly extinct, unless extant in the Indo-West Pacific)
Mollusca: Gastropoda		
<i>Haliotis cracherodii</i>	Eastern Pacific	Rocky shores (see Table 2)
<i>Siphonaria compressa</i>	South Africa	Eelgrass specialist in a few lagoons
Crustacea: Amphipoda		
<i>Ingolfiella longipes</i>	Bermuda	Brackish cave

Table 4 Marine invertebrate extinctions in historical time

Species	Former location	Last known living	Habitat/extinction cause
Mollusca: Gastropoda			
<i>Lottia alveus</i> (eelgrass limpet)	Northwest Atlantic: Labrador to New York	1929	Eelgrass (<i>Zostera marina</i>) blades; loss of habitat due to demise of eelgrass, due in turn to epidemic of eelgrass disease (natural resurgence or introduced?)
<i>Lottia edmittchelli</i> (shore limpet)	Southern California	1861	Rocky intertidal; habitat loss
<i>Littoraria flammea</i> (periwinkle)	China	<1840s	Mangrove and other intertidal habitats; probable habitat loss
<i>Cerithidea fuscata</i> (horn snail)	Southern California	1935	Estuarine mudflats; habitat loss

Source: Reproduced from Carlton JT, Geller JB, Reaka-Kudla ML, and Norse EA (1999) Historical extinction in the sea. *Annual Review of Ecology and Systematics* 30: 515–538.

common rocky shore limpet in Monterey Bay sometime before 1873, has not been seen in over 135 years, but is absent from virtually all discussions of marine endangered species (the genus name, newly proposed in 2009, refers to the mystery surrounding the species). The Mediterranean limpet *Patella ferruginea* is described as “the most endangered marine invertebrate species” on the European Council Directive on the Conservation of Natural Habitat of Wild Fauna and Flora but is absent from IUCN lists. These examples of differences in listings – and omissions or exclusions from different international and national registries – further underscore the challenges in properly assessing the status of many marine species and of appropriately assessing their standing independent of the political, economic, or other pressures.

Habitats and Species Susceptible to Endangerment

An examination of [Tables 2](#) and [3](#) and consideration of those few marine invertebrates known to have gone extinct ([Table 4](#))

provides some predictive power for those habitats and species that are at greatest risk ([Table 5](#)). Species with highly restricted distributions under heavy fisheries pressure or in habitats strikingly susceptible to human pressures would appear to be low-hanging fruit for investigation of their historical and modern population status. Species in habitats that could be eliminated *in toto* have likely suffered extensively even if their demise has gone unnoticed. A marine habitat that has been extensively altered and extirpated over the past several hundred years globally is the supralittoral zone (variously known also as the wrack, drift, or strand line). This ecotonal world supports – or supported – a large number of species of crustaceans, other arthropods, nemerteans, polychaete worms, gastropods, and other taxa found only in this unique habitat, but they are now replaced in many regions by carparks, seawalls, container ship terminals, housing developments, coastal roads, and so on. Finally, an unknown number of marine invertebrate symbionts, commensals, and parasites associated with endangered and vulnerable marine vertebrates, other invertebrates, and marine plants are without doubt themselves threatened.

Table 5 Marine invertebrates at risk of endangerment and extinction

Examples of risk groups	Examples of species
Species with restricted distributions Species restricted to lagoons, estuaries, isolated marshes and mangroves, remnant seagrass beds, and other limited or now-restricted coastal habitats	Seaslug <i>Phyllaplysia smaragda</i> Seaslug <i>Stilliger vossi</i> Limpet <i>Siphonaria compressa</i> Amphipod <i>Transorchestia enigmatica</i> Many other species in coastal habitats, including estuarine seagrass stenotopic endemics
Species with limited distributions under heavy extraction pressure or under pressure from related extraction activities (such as bottom trawling)	White abalone <i>Haliotis sorenseni</i> , certain benthic invertebrates in areas of heavy trawling, endemic coral reef species
Short-range endemics with non-planktotrophic development, especially those under extraction pressure, fisheries activities, or at risk from coastal development and pollution	Many invertebrates species in numerous phyla, including short-range cone snails (<i>Conus</i> spp.); endemic coral reef species (all invertebrates); species restricted to islands, offshore banks, and sea mounts
<i>Species restricted to extinguisable habitat</i> Invertebrates found only in supralittoral (maritime, strand, and wrack-line) habitats	Talitrid amphipods, oniscid isopods, staphylinid beetles, other beach insects, marine centipedes, pseudoscorpions, nemerteans, polychaetes
<i>Species associated with other endangered species</i> Commensals; symbionts; and parasites of endangered marine vertebrates, invertebrates, and plants	Species associated with ● Mammal: <i>Phocoena sinus</i> (Gulf of California vaquita) ● Fish: <i>Syngnathus affinis</i> (Texas pipefish) ● Fish: <i>Raja laevis</i> (barndoor skate) ● Bird: <i>Oceanodroma macrodactyla</i> (Guadalupe storm petrel)^a ● Other endangered marine vertebrates ● Endangered marine invertebrates ● Endangered marine plants

^aIf not already extinct.

Challenges with Determining the Number of Endangered Marine Invertebrates

Already mentioned is that disparate lists of threatened, endangered, and vulnerable lists of marine invertebrates (and all other marine species) exist in different countries and through different international organizations. Further impeding a clear view of the scale of endangerment and extinction is (despite the completion of a recent Census of Marine Life) a very limited picture of the historical baseline of nonedible marine invertebrate populations (accompanied by a striking lack of exploration of historical resources, such as earlier literature and museum collections), and the modern-day (the last 75 or so years) demise of marine invertebrate taxonomy, systematics, biogeography, and natural history. Perhaps underlying much of our general lack of understanding of the scale of endangerment and extinction among marine invertebrates is the enduring assumption that if common species have been on a steady decline, or had entirely disappeared, then “someone would have noticed.” Numerous accounts of the overlooked demise of many marine species (and, concomitantly, commonly overlooking additions to marine communities by way of newly invading species) argue otherwise.

Recovery Strategies: Extraction Management, Culture, and Transplantation

The often late recognition that overextracted populations are in severe decline, or are almost extirpated, is typically accompanied by government regulations that close or restrict fisheries long after the target species has passed into functional or commercial extinction. Thus, the endangered abalones of the California coast are now under strict regulation, and IUCN trade rules attempt to prohibit the international movement of many species of corals. Additional approaches to prevent species demise now also include growing attempts to culture species – such as corals – in the laboratory (with subsequent outplanting back in the wild), and proposals to transplant species to new regions (also known as “managed relocation” and “assisted migration”). The latter strategy, although not new, has stirred concerns about the possibility that such transplants could inadvertently lead to species becoming potential nuisance invaders. Thus, the marsh snail *Assiminea parasitologica*, considered a rare, threatened species (due to habitat loss) in Japan, was accidentally introduced in ships’ ballast water in the 1990s or early 2000s to the Oregon coast, where it now occurs by the billions, and threatens to replace a native marsh snail, *Assiminea californica*.

Glossary

Critical habitat Habitat of a threatened or endangered species that is itself threatened by destruction, disturbance, modification, or human activity, potentially resulting in a reduction in the numbers, distribution, or reasonable expansion or recovery of that species.

Endangered species Those species in danger of extinction throughout all or a significant portion of their range.

Endemism Condition in which a species' distribution is restricted to a given geographic region.

Rare species Species with small populations globally that are not presently listed as endangered or vulnerable, but are at risk because of their small population size.

Threatened species Those species that are likely to become endangered in the foreseeable future throughout all or a significant portion of their range.

Introduction

Extinction has always played an important role in nature: 95–99% of all species that ever existed are now extinct. It is the current rapid rate of extinction that has many plant ecologists worried. A recent global analysis by Royal Botanic Gardens, Kew together with the Natural History Museum, London and IUCN showed that over one fifth world's plant species are threatened with extinction (IUCN, 2010). Worldwide, as many as 654 species of plants have gone extinct since A.D. 1600 (Heywood, 1995). In this time period, about 110 plant species may have gone extinct in Hawaii according to records of the U.S. Fish and Wildlife Service and The Nature Conservancy. Estimates of plant extinctions in the continental United States range from below 25 (IUCN, 1998) to above 90 (Davis *et al.*, 1986; Flather *et al.*, 1994). The discrepancy in estimates is due to incomplete systematic surveys, limited monitoring activities, and poor information on viable seed banks. Estimates of extinctions in other countries include 71 plant species in Australia, 53 in South Africa, 47 in Mauritius, and 23 in Cuba. Three endemic species of ebony (*Diospyros* spp.) went extinct in the Mascarene Islands before they were described. Nuttall's mudwort (*Micranthemum micranthemoides*) had been recorded in Delaware, Maryland, New Jersey, New York, Pennsylvania, Virginia, and the District of Columbia, but, despite extensive searches it has not been seen since 1941. The single individual of *Dicliptera dodsonii*, which clings to life in western Ecuador (Gentry, 1986), may be the next victim of accelerated extinction.

Estimates of future plant species extinctions vary widely. Raven *et al.* (1986) estimated that about 40,000 tropical plant species may go extinct in the wild within the next several decades. The New York Botanical Garden suggests that about 700 of the more than 2000 species of threatened and endangered plant species in the United States may be extinct in the next 10 years. The Center for Plant Conservation reported that 680 U.S. plant species were critically endangered, with approximately 253 species estimated to become extinct in 5 years and 427 species to become extinct in 10 years (based on

unpublished data in 1988). Today, more than 20 years later, there is little evidence of these mass extinctions, but the concern may still be well founded in several areas.

Hawaii provides a good example of endangered plants. Up to 47% of the Hawaiian flora may meet the criteria for official listing by the U.S. Fish and Wildlife Service, with as many as 16% immediately threatened with extinction (see the [Missouri Botanical Garden](#) web-site listed in the References). The genus *Hibiscadelphus* in Hawaii includes only six species (with two extinct species) with a total of 14 live individuals, and one species with only one individual (Cody, 1986). The Hawaii Endangered Plant Task Force, which includes many federal, state, and non-government partners, now tracks 597 threatened, endangered, and rare plant species.

There is a growing backlog of candidates for listing as endangered species. Between July 1976 and August 1992, about 21 species per year were added to the U.S. endangered species list. In the second half of that 16-year period, 33 species per year were added to the list (Flather *et al.*, 1994). More than 200 plant species are being petitioned for future listing in the United States.

It has been said that “all species are rare somewhere” (Orians, 1997), because most plant species have larger populations in well-suited habitats and smaller populations in marginal or suboptimal habitats. Many threatened vascular plants in Finland were found to be rare largely because the species were in marginal rather than suitable habitat (Cropper, 1993). Along with the increasing threats of rapid environmental change, habitat loss, contaminants, and invasive exotic species, we may face an uphill battle in protecting our treasured botanical resources in these suboptimal habitats.

Maintaining biodiversity requires a considerable understanding of rarity and the processes and stresses that promote the endangerment of certain plant species. This article reviews the kinds of rarity, patterns of endangerment, causes of endangerment, consequences of rarity, and legal mandates to protect endangered plant species. It then provides selected examples of endangered plants, an example of a technique used for detection and mapping of endangered plants, and

concludes with the management and social implications of protecting endangered plants.

Kinds of Rarity

There are many published definitions of rarity. In an extreme example, DuMond (1973) stated nine criteria for rarity, including species that are: (1) found out of its expected context; (2) particularly subject to extinction or severe reduction in total population size by human activities that have already caused a significant population reduction; (3) found only in a very specific habitat of limited occurrence; (4) thought to be a relict of a no-longer extant vegetation association; (5) an indicator of a unique extant vegetation association; (6) recognized as an example of a wide, disjunction pattern; (7) at its natural distribution limits within the area in question; (8) known to be introduced and has become naturalized only on a very small scale; or (9) does not consistently occur as a member of any particular natural plant community. Gaston (1997) described rarity in another way, noting that rare species can be delimited on the basis of one, two, or at most a few of the following variables: abundance, range size, habitat specificity (habitat occupancy), temporal persistence (e.g., taxon age), threat (probability of, or time to, extinction), gene flow, genetic diversity, endemism, and taxonomic distinctness. Rare species in the IUCN Red Book (1998) are described in terms of population size rather than an assessment of extinction risk, which is reserved for threatened and endangered status. The Nature Conservancy and associated network of Natural Heritage Programs rate species endangerment based on five levels of global rarity (i.e., G1, G2, G3, etc.), national rarity (N1, N2, etc.), and state rarity (S1, S2, etc.).

The kinds of rarity that concern conservation biologists relate specifically to the potential vulnerability to extinction. Commonly recognized kinds of rarity (Rabinowitz, 1981; Cropper, 1993) include species with:

- Small populations, large geographic range, and occurrences in several habitats. For example, American chaffseed (*Schwalbea americana*) had a historical distribution from Mississippi to Massachusetts. It resides now in 20 relatively small populations in five states, with the greatest populations in South Carolina. It can survive in several vegetation types as long as there is enough light in the understory. Fire suppression, which allows for succession and canopy closure, threatens several *Schwalbea* populations. Another example is *Hypochoeris maculata*, which has small populations over a wide range in Great Britain.
- Large populations, large geographic range, but occurrences in specific habitats. For example, several grassland species of *Calochortus* (lilies) in California have large populations following wildfires. They were thought to be far more widespread prior to a century of fire suppression and encroachment of shrubs into grassland habitats. Sparse populations in a large geographic range but in specific habitats. For example, *Psilotum nudum* grows only on rocky outcrops and always in sparse populations, but it occurs in Australia, New Zealand, and Easter Island (Cropper, 1993).
- Small geographic range, but locally abundant in specific habitats. For example, the 48 endemic species of Bignoniaceae in Amazonia have a total home range of only a few thousand square kilometers, but some of these species are locally abundant in restricted habitats (Gentry, 1986). A specific example in Scotland is *Primula scotica*, which has a tiny range with a few large populations.
- Small geographic range, and sparse in specific habitats. This may be the most critical type of rarity, for small populations restricted to small and specific habitats are highly vulnerable to extinction. For example, the scouring of a new stone quarry in South Africa ended life in the wild for *Moraea loubseri*, a small, sparse-population iris (Stermer, 1995).
- Small populations of concern in any region despite populations elsewhere. For example, many floristically poor northern European countries typically have 200 or more plant species listed as threatened or endangered. However, many of these species invaded broadly since the last Ice Age, and they are buffered from extinction with widely scattered populations in several countries (Davis *et al.*, 1986).
- Small populations of new species. For example, a newly discovered species of *Calypttranthes* from El Yunque, Puerto Rico, has a population of four trees, and *Auerodendron pauciflorum* from Quebradillas and *Calypttranthes luquillensis* from the Luquillo Mountains have only five individuals each (Cody, 1986).

Generally, species may be ranked for protection based on overall rarity, magnitude of potential threats to populations, and the immediacy of the threats. Thus, a monotypic genus with high-magnitude and imminent threats might receive a higher priority ranking than a subspecies with moderate or nonimminent potential threats.

Endangerment Patterns

Slightly over 90% of threatened plants are single-country endemics. Species with restricted ranges face the greatest threat of extinction. It follows that endemic plant species on islands appear to be the most highly endangered. About 95% of the plant species on the Canary Islands are endemic, and 50% are considered endangered (Cody, 1986). *Senecio heritieri*, for example, is restricted to a small area of rocky slopes on the south coast of the island of Tenerife, one of the Canary Islands. On Crete, two-thirds of the 155 endemic species are endangered (Cody, 1986). Compare these numbers to those of the entire United States, where there are about 20,000 plant species of which 2050 species are rare and threatened.

About half the plant species in Mediterranean climate areas (parts of California, South Africa, Australia, and the Mediterranean basin) are narrow endemics that dominate the threatened and endangered species lists in their various countries (Figure 1) (Davis *et al.*, 1986). California, for example, contains 669 endemic species of the 2050 species on the U.S. rare and threatened list (Davis *et al.*, 1986). Chile has 50 forest tree species; 47 of these species are endemic and 38 species are listed as endangered, vulnerable, or rare.

Over half of the rare and endangered plants of the continental United States grow within the borders of 12 western

Figure 2 Distribution of rare plants in the continental United States. The “top 10” continental states for rare plants include six western states, and California clearly dominates. Reproduced from Flather CH, Knowles MS, and Kendall IA (1998) Threatened and endangered species geography. *BioScience* 48: 365–376.

states (Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Texas, Utah, Oregon, Washington, and Wyoming; **Figure 2**) (Flather *et al.*, 1994). However, among U.S. states Hawaii is the hot spot of endangerment: about 950 native plant species of Hawaii are extinct, endangered, or threatened (Raven *et al.*, 1986).

Endangerment patterns vary by habitat type. Flather *et al.* (1994) reported that 44% of threatened and endangered plants in the continental United States are found in rangelands. Twenty-five percent of endangered plant species were

associated with barren land or rocky habitats. However, wetlands, which comprise only 5% of the land base, contain 15% of the listed species.

Endangerment patterns also vary by region and land-use characteristics. In northern California, southern Nevada/Sonoran Basin, and the eastern Gulf Coast, >50% of the listed species are associated with wetland habitats. U.S. Department of Defense lands, which comprise only 3.4% of federally administered lands, contain 26% of the listed species. The high number of rare plants in the U.S. Southwest when combined

with rapid development and land-use change, leads to special problems for the western states that wish to conserve their floral heritage.

Worldwide, Australia and New Zealand have attracted much attention. Official listings show 1931 endangered plant species in Australia and 22 species in New Zealand (Stermer, 1995). Australia has already lost 117 plant species to extinction in modern times (Davis *et al.*, 1986), and has 3329 plant species that are considered rare or threatened (6.2% of the flora). An estimated 993 species are at risk of extinction in the next 50 years (Cropper, 1993).

Some plant families and genera are more prone to extinction than others. Twenty vascular plant families have at least 50% of their species threatened (e.g., Brunelliaceae, 91.9%; Zamiaceae, 88.9%; Araucariaceae, 78.9%; Taxaceae, 75%; Limnanthaceae, 72.7%). In Australia, species-rich genera such as *Acacia*, *Eucalyptus*, and *Grevillia* contain a proportionally greater number of rare species than do species-poor genera. Gymnosperms, containing relatively ancient species, may be less adapted to today's rapidly changing environment (IUCN, 1998). Cacti in the United States are particularly prone to extinction: 72 of 268 native species are very rare (Benson, 1982). In California, shrubs and subshrubs of the species-rich genera *Arctostaphylos*, *Ceanothus*, *Eriogonum*, and *Ribes* have a higher proportion of threatened and endangered plants relative to their proportion in the flora (Cody, 1986).

Curiously, some rare plant habitats may have human origins. Some moorlands, or blanket bogs, in western Europe were created around 7700 years ago by human activities of burning and grazing. These heathlands and grasslands today support many endangered plant species.

Causes of Endangerment

There are several natural causes of rarity that lead to endangerment. Ancient taxa, like cycads, are thought to be prone to extinction as they cling to increasingly shrinking relict habitats. New taxa, resulting from recent speciation, are thought to be susceptible to extinction because they have not had time to spread in distribution to reduce risk. Rare species generally lack an ability to rapidly colonize areas and they are often poor competitors. Many rare species are edaphically restricted to specific soils or geology. However, based on recent rates of extinction, natural causes of rarity (individually or combined) are no match for human-related causes of endangerment.

Species usually become endangered because of multiple, human-related causes. The overwhelming cause of plant species endangerment is habitat loss, directly linked to agriculture, forestry, and urbanization. Remaining small populations have a higher risk of extirpation (local extinction) or extinction. Coinciding with habitat loss is reduced habitat quality related to invasive species, grazing, and other land-use changes (Flather *et al.*, 1994). There are many examples of habitat loss to choose from. In the wetter forested Sierra Madres of Mexico, Guatemalan fir (*Abies guatemalensis*) or Pinabete trees are considered endangered from over-exploitation of old-growth forests, land-use change, and livestock grazing (Burton, 1991). *Persea theobromifolia*, once an important timber species in western Ecuador, has been reduced to

fewer than 12 trees at Rio Palenque (Gentry, 1986). In the United States Burton (1991) reported that only 1% of the 1,036,000 km² (400,000 mi²) of tallgrass prairie remains, now existing in isolated patches and small nature reserves. Over half of all continental U.S. wetland and aquatic habitats have been destroyed. Fire suppression and succession, invasive exotic plants, and habitat fragmentation will make it increasingly difficult for rare species to persist.

Causes of rarity vary by region. Though habitat loss was generalized as an overall problem, agricultural development was specifically noted in the southern Appalachian region, whereas urban development and forest clearing were specifically noted in Florida. In the Gulf Coast areas, shoreline modification and development were specifically noted in endangerment patterns (Flather *et al.*, 1994).

Commercial exploitation is also a problem. Cacti in the southwestern United States are a prime example. Legislation regulating the collection of cacti in Arizona and California date from 1929. Yet, in a single year, over half a million small cacti were illegally collected for sale in the United States, Japan, and Europe (Burton, 1991). One of the two colonies of the 2.5-cm-diameter Nellie Cory cactus (*Coryphantha minima*) was completely eliminated by thieves in the 1960s. The rarest species demand the highest prices from collectors. Rare orchids are plucked one by one by various "collectors." Some threatened orchids in India, such as *Paphiopedilum druri*, *Dendrobium pauciflorum*, *Dendrobium nobile*, and *Diplomeris hirsuta*, are used for medicinal purposes. As such, they are facing increasing pressure from growing and aging human populations.
